Chapter 1. Introduction to Specware

1.1. What Is Specware?

Specware is a tool for building and manipulating a collection of related specifications. Specware can be considered:

- a design tool, because it can represent and manipulate designs for complex systems, software or otherwise
- a logic, because it can describe concepts in a formal language with rules of deduction
- a programming language, because it can express programs and their properties
- a database, because it can store and manipulate collections of concepts, facts, and relationships

Specifications are the primary units of information in Specware. A specification, or theory, describes a concept to some degree of detail. To add properties and extend definitions, you create new specifications that import or combine earlier specifications. Within a specification, you can reason about objects and their relationships. You declare sorts (data types) and operations (ops, functions), axioms that state properties of operations, and theorems that follow logically from axioms.

A morphism is a relationship between specifications that describes how the properties of one map to the properties of another. Morphisms describe both part-of and is-a relationships. You can propagate theorems from one specification to another using morphisms; for example, if the QEII is a ship, and ships cannot fly, then the QEII cannot fly.

1.2. What Is Specware For?

Specware is a general-purpose tool that you can use to develop specifications for any system or realm of knowledge. You can do this as an abstract process, with no reference to computer programming; or you can produce a computer program that is provably a correct implementation of a specification; or you can use the process to redesign an existing program.

You can use Specware to:

· Develop domain theories

You can use Specware to do "ontological engineering" -- that is, to describe a real-world domain of knowledge in explicit or rigorous terms. You might wish to develop a domain theory in abstract terms that are not necessarily intended to become a computer program. You can use the inference engine to test the internal logic of your theory, derive conclusions, and propose theorems.

You can use specifications and morphisms to represent abstract knowledge, with no refinement to any kind of concrete implementation.

More commonly, you would use Specware to model expert knowledge of engineering design. In this case you would refine your theoretical specifications and morphisms to more concrete levels.

• Develop code from specifications

You can use Specware to develop computer programs from specifications. One advantage of using Specware for this task is that you can prove that the generated code does implement the specification correctly. Another advantage is that you can develop and compare different implementations of the same specification.

• Develop specifications from code

You can use Specware for reverse engineering -- that is, to help you derive a specification from existing code. To do this, you must examine the code to determine what problems are being solved by it, then use Specware's language Metaslang to express the problems as specifications. In addition to providing a notation tool for this process, Specware allows you to operate on the derived specification. Once you have derived a specification from the original code, you can analyze the specification for correctness and completeness, and also generate different and correct implementations for it.

1.3. The Design Process in Specware

To solve real problems, programs typically combine domain theories about the physical world with problem solving theories about the computational world. Your domain theory is an abstract representation of a real-world problem domain. To implement it,

you must transform the domain theory to a concrete computational model. The built-in specification libraries describe mathematical and computational concepts, which are building blocks for an implementation. Your specifications combine real-world knowledge with this built-in computational knowledge to generate program code that solves real-world problems in a rigorous and provable way.

You interpret designs relative to an initial universe of models. In software design, for example, the models are programs, while in engineering design, they are circuits or pieces of metal. To design an object is to choose it from among the universe of possible models. You make this choice by beginning with an initial description and augmenting it until it uniquely describes the model you desire. In Specware, this process is called refinement.

Composition and refinement are the basic techniques of application building in Specware. You compose simpler specifications into more complex ones, and refine more abstract specifications into more concrete ones. When you refine a specification, you create a more specific case of it; that is, you reduce the number of possible models of it.

The process of refinement is also one of composition. To begin the refinement, you construct primitive interpretations that show how to implement an abstract concept in terms of a concrete concept. You then compose interpretations to deepen and widen the refinement.

Specware provides two types of composition for interpretations; horizontal (or parallel), and vertical (or sequential).

- When you compose interpretations horizontally, you increase the scope of what is refined. In the same way you compose specifications to create a more complex specification from simpler parts, you compose refinements horizontally to create a complex refinement from simpler parts.
- When you compose interpretations vertically, you increase the degree of refinement. You compose interpretations sequentially, in a simple, linear progression, to create a deeper refinement from a shallower one.

For example, suppose you are designing a house. A wide but not deep view of the design specifies several rooms but gives no details. A deep but not wide view of the design specifies one room in complete detail. To complete the refinement, you must create a view that is both wide and deep; however, it makes no difference which view you create first.

The final refinement implements a complex, abstract specification by interpreting it to code.

1.4. Stages of Application Building

Conceptually, there are two major stages in producing a Specware application. In the actual process, steps from these two stages may alternate.

- 1. Building a specification
- 2. Refining your specifications to constructive specifications

1.4.1. Building a Specification

You must build a specification that describes your domain theory in rigorous terms. To do this, you first create small specifications for basic, abstract concepts, then specialize and combine these to make them more concrete and complex.

To relate concepts to each other in Specware, you use specification morphisms. A specification morphism shows how one concept is a specialization or part of another. For example, the concept "fast car" specializes both "car" and "fast thing". The concept "room" is part of the concept "house". You can specialize "room" in different ways, one for each room of the house.

You specialize in order to derive a more concrete specification from a more abstract specification. Because the specialization relation is transitive (if A specializes B and B specializes C, then A specializes C as well), you can combine a series of morphisms to achieve a step-wise refinement of abstract specifications into increasingly concrete ones.

You combine specifications in order to construct a more complex concept from a collection of simpler parts. In general, you increase the complexity of a specification by adding more structural detail.

Specware helps you to handle complexity and scale by providing composition operators that take small specifications and combine them in a rigorous way to produce a complex specification that retains the logic of its parts. Specware provides several techniques for combining specifications, that can be used in combination:

- The import operation allows you to include earlier specifications in a later one.
- The translate operation allows you to rename the parts of a specification.
- The colimit operation glues concepts together into a shared union along shared subconcepts.

A shared union specification combines specializations of a concept. For example, if you combine "red car" with "fast car" sharing the concept "car", you obtain the shared union "fast, red car". If you combine them sharing nothing, you obtain "red car and fast car", which is two cars rather than one. Both choices are available.

1.4.2. Refining your specifications to constructive specifications

You combine specifications to extend the refinement iteratively. The goal is to create a refinement between the abstract specification of your problem domain and a concrete implementation of the problem solution in terms of sorts and operations that ultimately are defined in the Specware libraries of mathematical and computational theories.

For example, suppose you want to create a specification for a card game. An abstract specification of a card game would include concepts such as card, suit, and hand. A refinement for this specification might map cards to natural numbers and hands to lists containing natural numbers.

The Specware libraries contains constructive specifications for various sorts, including natural numbers and lists.

To refine your abstract specification, you build a refinement between the abstract Hand specification and the List-based specification. When all sorts and operations are refined to concrete library-defined sorts and operations, the Specware system can generate code from the specification.

1.5. Reasoning About Your Code

Writing software in Metaslang, the specification and programming language used in Specware, brings many advantages. Along with the previously-mentioned possibilities for incremental development, you have the option to perform rigorous verification of the design and implementation of your code, leading to the a high level of assurance in the correctness of the final application.

1.5.1. Abstractness in Specware

Specware allows you to work directly with abstract concepts independently of

Chapter 1. Introduction to Specware

implementation decisions. You can put off making implementation decisions by describing the problem domain in general terms, specifying only those properties you need for the task at hand.

In most languages, you can declare either everything about a function or nothing about it. That is, you can declare only its type, or its complete definition. In Specware you must declare the signature of an operation, but after that you have almost complete freedom in stating properties of the operation. You can declare nothing or anything about it. Any properties you have stated can be used for program transformation.

For example, you can describe how squaring distributes over multiplication:

```
axiom square_distributes_over_times is
  fa(a, b) square(a * b) = square(a) * square(b)
```

This property is not a complete definition of the squaring operation, but it is true. The truth of this axiom must be preserved as you refine the operation. However, unless you are going to generate code for square, you do not need to supply a complete definition.

The completeness of your definitions determines whether you can create interpretations to code. An interpretation must completely define the operations of the source theory in terms of the target theory. This guarantees that, if the target is implementable, the source is also implementable. However, Specware also allows you to construct interpretation schemes, which need not be definitional extensions. This allows you to make considerable progress in building up and refining an abstract specification in advance of providing complete definitions.

1.5.2. Logical Inference in Specware

Specware performs inference using external theorem provers; the distribution includes SRI's SNARK theorem prover. External provers are connected to Specware through logic morphisms, which relate logics to each other.

You can apply external reasoning agents to refinements in different ways (although only verification is fully implemented in the current release of Specware).

- Verification tests the correctness of a refinement. For example, you can prove that quicksort is a correct refinement of the sorting specification.
- Simplification is a complexity-reducing refinement. For example, given appropriate axioms, you can rewrite 3*a+3*b to 3*(a+b).

• Synthesis derives a refinement for a given specification by combining the domain theory with computational theory. For example, you can derive quicksort semi-automatically from the sorting specification as a solution to a sorting problem, if you describe exactly how the problem is a sorting problem.

Chapter 1. Introduction to Specware

This chapter introduces the Metaslang specification language.

The following sections give the grammar rules and meaning for each Metaslang language construct.

2.1. Preliminaries

2.1.1. The grammar description formalism

The grammar rules used to describe the Metaslang language use the conventions of (extended) BNF. For example, a grammar rule like:

```
wiffle ::= waffle [ waffle-tail ] | piffle { + piffle }*
```

defines a wiffle to be: either a waffle optionally followed by a waffle-tail, or a sequence of one or more piffles separated by terminal symbols + . (Further rules would be needed for waffle, waffle-tail and piffle.) In a grammar rule the left-hand side of : = shows the kind of construct being defined, and the right-hand side shows how it is defined in terms of other constructs. The sign | separates alternatives, the square brackets [...] enclose optional parts, and the curly braces plus asterisk { ... } * enclose a part that may be repeated any number of times, including zero times. All other signs stand for themselves, like the symbol + in the example rule above.

In the grammar rules terminal symbols appear in a bold font. Some of the terminal symbols used, like | and {, are very similar to the grammar signs like | and { as described above. They can hopefully be distinguished by their bold appearance.

Grammar rules may be *recursive*: a construct may be defined in terms of itself, directly or indirectly. For example, given the rule:

```
piffle ::= 1 | M { piffle }*
```

here are some possible piffles:

1 M M1 M111 MMMM M1M1

Note that the last two examples of piffles are ambiguous. For example, M1M1 can be interpreted as: M followed by the two piffles 1 and M1, but also as: M followed by the

three piffles 1, M, and another 1. Some of the actual grammar rules allow ambiguities; the accompanying text will indicate how they are to be resolved.

2.1.2. Models

```
spec ::= spec-form
op ::= op-name
```

The term spec is used as short for spec-form. The *semantics* of Metaslang specs is given in terms of classes of *models*. A model is an assignment of sets of values (called "sorts") to all the sort-names and of "sorted" values to all the op-names declared --explicitly or implicitly -- in the spec. The notion of *value* includes numbers, strings, arrays, functions, etcetera. A sorted value can be thought of as a pair (S, V), in which S is a sort and V is a value that is an inhabitant of S. For example, the expressions O:

Nat and O: Integer correspond, semantically, to the sorted values (N, O) and (Z, O), respectively, in which N stands for the set of natural numbers $\{0, 1, 2, ...\}$, and Z for the set of integers $\{..., -2, -1, 0, 1, 2, ...\}$. (For historical reasons, the term *sort* is traditionally used in specification languages with essentially the same meaning as the term *type* in programming languages.) In Metaslang, OP is used -- again for historical reasons -- for declared names representing values. The term "op" is used as an abbreviation for "op-name". (OP for OP-rator, a term used, again, for historical reasons, although including things normally not considered operators.) For example, given this Spec:

```
spec
  sort Even
  op next : Even -> Even
  axiom nextEffect is
    fa(x : Even) ~(next x = x)
endspec
```

one possible model (out of many!) is the assignment of the even integers to Even, and of the function that increments an even number by 2 to next.

Each model has to *respect sorting*; for example, given the above assignment to Even, the function that increments a number by 1 does not map all even numbers to even numbers, and therefore can not -- in the same model -- be assigned to next. Additionally, the axioms of the spec have to be satisfied by the model. The axiom labeled nextEffect above states that the function assigned to op-name next maps

any value of the sort assigned to **sort-name** Even to a different value. So the squaring function, although sort-respecting, could not be assigned to next since it maps 0 to itself.

If all sort-respecting combinations of assignments of sorts to sort-names and ops to op-names fail the axioms test, the spec has no models and is called *inconsistent*. Although usually undesirable, an inconsistent spec is not by itself considered erroneous. The Specware system does not attempt to detect inconsistencies, but associated provers can sometimes be used to find them. Not always; in general it is undecidable whether a spec is consistent or not.

In general, the meaning of a construct in a model depends on the assignments of that model, and more generally on an *environment*: a model possibly extended with assignments to local-variables. For example, the meaning of the claim fa(x):

Even) \sim (next x = x) in the axiom nextEffect depends on the meanings of Even and next, while the sub-expression next x, for example, also depends on an assignment (of an "even" value) to x. To avoid laborious phrasings, the semantic descriptions use language like "the function next applied to x" as shorthand for this lengthy phrase: "the function assigned in the environment to next applied to the value assigned in the environment to x".

When an environment is extended with an assignment to a local-variable, any assignments to synonymous ops or other local-variables are superseded by the new assignment in the new environment. In terms of Metaslang text, within the scope of the binding of local-variables, synonymous ops and earlier introduced local-variables (that is, having the same name) are "hidden"; any use of the name in that scope refers to the textually most recently introduced local-variable. For example, given:

```
def x = "op-x"
def y = let v = "let-v" in x
def z = let x = "let-x" in x
```

the value of y is "op-x" (op x is not hidden by the local-variable v of the let-binding), whereas the value of z is "let-x" (op x is hidden by the local-variable x of the let-binding).

2.1.3. Sort-correctness

Next to the general requirement that each model respects sorting, there are specific correctness requirements for various constructs that constrain the possible sorts for the components. For example, in an application f(x), the sort of the actual-parameter x

has to match the domain sort of function f. These requirements are stated in the relevant sections of this language manual. If no sort-respecting combinations of assignments meeting all these requirements exist for a given spec, it is considered *incorrect*, and is said to have a sort error (or type error). This is determined by Specware while elaborating the spec, and signaled as an error. Sort-incorrectness differs from inconsistency in that the meaning of the axioms does not come into play, and the question whether an incorrect spec is consistent is moot.

To be precise, there are subtle and less subtle differences between sort-incorrectness of a spec and its having no sort-respecting combinations of assignments. For example, the following spec is sort-correct but has no models:

```
spec
  sort Empty = | Just Empty
  op IdoNotExist : Empty
endspec
```

The explanation is that the **sort-definition** for Empty generates an *implicit* axiom that all inhabitants of the sort Empty must satisfy, and for this recursive definition the axiom effectively states that such creatures can't exist: the sort Empty is uninhabited. That by itself is no problem, but precludes a sort-respecting assignment of an inhabitant of Empty to Op IdoNotExist. So the Spec, while sort-correct, is actually inconsistent. See further under *Sort-definitions*.

Here is a sort-incorrect **spec** that has sort-respecting combinations of assignments:

```
spec
  sort Outcome = | Positive | Negative
  sort Sign = | Positive | Zero | Negative
  def whatAmI = Positive
endspec
```

Here there are two constructors Positive of different sorts, the sort Outcome and the sort Sign. That by itself is fine, but when such "overloaded" constructors are used, the context must give sufficient information which is meant. Here, the use of Positive in the definition for op whatAmI leaves both possibilities open; as used it is sort-ambiguous. Metaslang allows omitting sort information provided that, given a sort assignment to all local-sort-variables in scope, unique sorts for all sorted constructs, such as expressions and patterns, can be inferred from the context. If no complete and unambiguous sort-assignment can be made, the Spec is not accepted by the Specware system. Sort-ambiguous expressions can be disambiguated by using a sort annotation, as described under Annotated-expressions. In the example, the definition of whatAmI can be disambiguated in either of the following ways:

```
def whatAmI : Sign = Positive
def whatAmI = Positive : Sign
```

Also, if the spec elsewhere contains something along the lines of:

```
op signToNat : Sign -> Nat def sw = signToNat whatAmI
```

that is sufficient to establish that whatAmI has sort Sign and thereby disambiguate the use of Positive. See further under *Op-definitions* and *Structors*.

2.1.4. Constructive

When code is generated for a spec, complete "self-contained" code is only generated for sort-definitions and op-definitions that are fully *constructive*.

Non-constructiveness is "contagious": a definition is only constructive if all components of the definition are. The sort of a sort-name without definition is not constructive. A sort is only constructive if all component sorts are. An op without definition is non-constructive, and so is an op whose sort is non-constructive. A quantification is non-constructive. The built-in polymorphic equality predicate = is only constructive for *discrete sorts* (see below).

A sort is called discrete if the equality predicate = for that sort is constructive. The built-in sorts Integer, Nat, Boolean, Char and String are all discrete. Sort List S is discrete when S is. All function sorts are non-discrete (even when the domain sort is the unit sort). Sum sorts, product sorts and record sorts are discrete whenever all component sorts are. Subsort $(S \mid P)$ is discrete when supersort S is. (Predicate P need not be constructive: the equality test is that of the supersort.) Quotient sort $S \mid Q$ is discrete when predicate Q is constructive. (Sort S need not be discrete: the equality test on the quotient sort is just the predicate Q applied to pairs of members of the Q-equivalence classes.)

2.2. Lexical conventions

A Metaslang text consists of a sequence of symbols, possibly interspersed with whitespace. The term *whitespace* refers to any non-empty sequence of spaces, tabs, newlines, and comments (described below). A symbol is presented in the text as a sequence of one or more "marks" (ASCII characters). Within a composite (multi-mark)

symbol, no whitespace is allowed, but whitespace may be needed between two symbols if together they could be taken for one symbol; in particular, two names that follow each other should be separated by whitespace. More precisely, whitespace is required between two adjacent symbols for each of the following combinations, in which "abc" stands for an arbitrary word-symbol, "<*>" stands for an arbitrary non-word-symbol starting with a ?-mark, and "123" stands for an arbitrary literal (see below for the definitions of the various classes of symbols):

```
abc abc
abc ?:!
abc 123
<*> <*> 123
abc
123 123
abc
( *
```

Apart from the last two cases, no whitespace is ever needed adjacent to a special-symbol.

Inside literals (constant-denotations) whitespace is also disallowed, except for "significant-whitespace" as described under *String-literals*.

Other than that, whitespace -- or the lack of it -- has no significance. Whitespace can be used to lay-out the text for readability, but as far as only the meaning is concerned, the following two presentations of the same Spec are entirely equivalent:

```
spec
  sort Even
  op next : Even -> Even
  axiom nextEffect is
    fa(x : Even) ~(next x = x)
endspec

spec sort Even op next : Even -> Even axiom nextEffect
is fa(x : Even)~(next x = x)endspec
```

2.2.1. Symbols and Names

```
symbol ::= name | literal | special-symbol
name ::= word-symbol | non-word-symbol
word-symbol ::= word-start-mark { word-continue-mark } *
word-start-mark ::= letter
word-continue-mark ::=
    letter | decimal-digit | ?
letter ::=
       A | B | C | D | E | F | G | H | I | J | K | L | M
     |\  \, N\  \, |\  \, O\  \, |\  \, P\  \, |\  \, Q\  \, |\  \, R\  \, |\  \, S\  \, |\  \, T\  \, |\  \, U\  \, |\  \, V\  \, |\  \, W\  \, |\  \, X\  \, |\  \, Y\  \, |\  \, Z
     | a | b | c | d | e | f | g | h | i | j | k | 1 | m
     | n | o | p | q | r | s | t | u | v | w | x | y | z
decimal-digit ::= 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9
non-word-symbol ::= non-word-mark { non-word-mark }*
non-word-mark ::=
     ' | ~ | ! | @ | $ | ^ | & | * | - | = | + | \ | | | : | < | > | / | ?
Sample names:
                                                    ?!
    Date
    yymmdd2date
    well_ordered?
                                   ~==
```

For convenience, here are the 14 printing ASCII marks that, next to letters and decimal-digits, can *not* occur in a non-word-symbol:

Restriction. As mentioned before, no whitespace is allowed in symbols: while anode is a single name, both a node and an ode consist of two names. Further, the case

(lower or upper) of letters in names is significant: grandparent, grandParent and grandpaRent are three different names.

Restriction. In general, names can be chosen freely. However, the following *reserved* words have a special meaning and must not be used for names:

as	endspec	infixr	relax
axiom	ex	is	restrict
case	fa	let	sort
choose	false	morphism	spec
colimit	fn	obligations	then
conjecture	from	of	theorem
def	generate	op	translate
diagram	if	project	true
else	import	prove	where
embed	in	qualifying	
embed?	infixl	quotient	

They each count as a single symbol, and no whitespace is allowed inside any reserved word.

Likewise, the following *reserved non-words* must not be used for names:

In addition, several names -- for example = -- are pre-defined in built-in libraries. While strictly speaking not reserved, they must not be redefined. See further the *Libraries* Appendix.

The non-word-symbols can be used to choose convenient names for infix operators that, conventionally, are written with non-alphabetic marks.

Some Metaslang users follow the convention of using names that start with a capital letter for unit-identifiers and sort-names and for constructors, while word-symbols chosen for op-names and field-names start with a lower-case letter. Both plain local-variables and local-sort-variables are often chosen to be single lower-case letters: x, y, z, a, b, c, with the start of the alphabet preferred for local-sort-variables. Op-names of predicates (that is, having some sort $S \rightarrow Boolean$) often end with the mark? These are just conventions that users are free to follow or ignore, but in particular some convention distinguishing constructors from op-names and local-variables is recommended.

2.2.2. Comments

```
comment ::= line-end-comment | block-comment
line-end-comment ::= % line-end-comment-body
line-end-comment-body ::=
    any-text-up-to-end-of-line

block-comment ::= (* block-comment-body *)

block-comment-body ::=
    any-text-including-newlines-and-nested-block-comments

Sample comments:
    % keys must be unique
    (* op yymmdd2Date : String -> Date *)
```

Metaslang allows two styles of comments. The %-style is light-weight, for adding comment on a line *after* the formal text (or taking a line on its own, but always confined to a single line). The (*...*)-style can be used for blocks of text, spanning several lines, or stay within a line. Any text remaining on the line after the closing *) is processed as formal text. Block-comments may be nested, so the pairs of brackets (* and *) must be balanced.

A block-comment can not contain a line-end-comment and vice versa: whichever starts first has "the right of way". For example, (* 100 % or more! *) is a block-comment with block-comment-body 100 % or more! . The % here is a mark like any other; it does not introduce a line-end-comment. Conversely, in the line-end-comment % op <*> stands for (*) the (* is part of the line-end-comment-body; it does not introduce a block-comment. Note also that % and (* have no special significance in literals (which may not contain whitespace, including comments): "100 % or more!" is a well-formed string-literal.

2.3. Units

A "unit" is an identifiable unit-term, where "identifiable" means that the unit-term can be referred to by a unit-identifier. Unit-terms can be "elaborated", resulting in specs,

morphisms, diagrams or other entities. The effect of elaborating a unit-definition is that its unit-term is elaborated and becomes associated with its unit-identifier.

A Specware project consists of a collection of Metaslang unit-definitions. They can be recorded in one or more Specware files. There are basically two styles for recording unit-definitions using Specware files. In the single-unit style, the file, when processed by Specware, contributes a single unit-definition to the project. In the multiple-unit style, the file may contribute several unit-definitions. The two styles may be freely mixed in a project (but not in the same Specware file). This is explained in more detail in what follows.

Unit-definitions may use other unit-definitions, including standard libraries, which in Specware 4.0 are supposed to be part of each project. However, the dependencies between units must not form a cycle; it must always be possible to arrange the unit-definitions in an order in which later unit-definitions only depend on earlier ones. How unit-definitions are processed by Specware is further dealt with in the Specware User Manual.

As mentioned above, unit-definitions are collected in Specware files, which in Specware 4.0 must have an .sw extension. The Specware files do not directly contain the unit-definitions that form the project. In fact, a user never writes unit-definition explicitly. These are instead determined from the contents of the Specware files using the following rules. There are two possibilities here. The first is that the specware-file-contents consists of a single unit-term. If P. sw is the path for the

Specware file, the unit being defined has as its unit-identifier *P*. For example, if file C:/units/Layout/Fixture.sw contains a single unit-term *U*, the unit-identifier is /units/Layout/Fixture, and the unit-definition it contributes to the project is

```
/units/Layout/Fixture = U
```

(Note that this is not allowed as an infile-unit-definition in a specware-file-contents, since the unit-identifier is not a fragment-identifier.)

The second possibility is that the Specware file contains one or more infile-unit-definitions. If \mathcal{I} is the fragment-identifier of such an infile-unit-definition, and \mathcal{P} . sw is the path for the Specware file, the unit being defined has as its unit-identifier $\mathcal{P}\#\mathcal{I}$. For example, if file \mathcal{C} : /units/Layout/Cart.sw contains an infile-unit-definition \mathcal{P} os = \mathcal{U} , the unit-identifier is /units/Layout/Cart# \mathcal{P} os, and the unit-definition it contributes to the project is

```
/units/Layout/Cart#Pos = U
```

2.3.1. Unit Identifiers

```
unit-identifier ::= swpath-based-path | relative-path
swpath-based-path ::= / relative-path
relative-path ::= { path-element / }* path-element [ # fragment-identifier ]
path-element ::= word-symbol
```

Warning. Note that unit-identifiers are processed by the tokenizer like everything else. This means that whitespace is removed and marks not allowed in word-symbols, even if otherwise permitted in filenames (such as .), cannot appear in unit-identifiers. For this reason, some care must be taken when naming units.

Unit-identifiers are used to identify unit-terms. Typically, only a final part of the full unit-identifier is used. When Specware is started with environment variable SWPATH set to a semicolon-separated list of pathnames for directories, the Specware files are searched for relative to these pathnames; for example, if SWPATH is set to C:/units/Layout/Cart, then

C:/units/Layout/Fixture.sw may be shortened to /Fixture, and
C:/units/Layout/Cart.sw to /Cart. How unit-definitions are processed by
Specware is further dealt with in the Specware User Manual.

Further, unit-identifiers can be relative to the directory containing the Specware file in which they occur. So, for example, both in file C:/units/Layout/Fixture.sw and in file C:/units/Layout/Cart.sw, unit-identifier Tools/Pivot refers to the unit-term contained in file C:/units/Layout/Tools/Pivot.sw, while Props#SDF refers to the unit-term of infile-unit-definition SDF = ... contained in file C:/units/Layout/Props.sw. As a special case, a unit-term with the same name as the file may be referenced without a fragment-identifier. For example, in the current case, if the file C:/units/Layout/Props.sw contains the unit-term of infile-unit-definition Props = ..., then this unit-term can be referred to either by Props#Props or Props.

The unit-identifier must identify a unit-definition as described above; the elaboration of the unit-identifier is then the result of elaborating the corresponding unit-term, yielding a Spec, morphism, diagram, or other entity.

2.3.2. Specs

```
spec-term ::=
    unit-identifier
    | spec-form
    | spec-qualification
    | spec-translation
    | spec-substitution
    | diagram-colimit
    | obligator
```

Restriction. When used as a spec-term, the elaboration of a unit-identifier must yield a spec.

The elaboration of a spec-term, if defined, yields a "closed" spec-form as defined in the next subsection.

2.3.2.1. Spec Forms

```
spec-form ::= spec { declaration }* endspec
```

Restriction. Spec-forms must be sort-correct.

Sample spec-forms:

spec import Measures import Valuta endspec

A *closed* spec-form is a spec-form containing no import-declarations.

The elaboration of a spec-form yields the Metaslang text which is that spec itself, after expanding any import-declarations. The *meaning* of that text is the class of models of the spec, as described throughout this Chapter.

2.3.2.2. Qualifications

Names of sorts and ops may be *unqualified* or *qualified*. The difference is that unqualified-names do not contain a dot sign ".", while qualified-names are prefixed with a "qualifier" followed by a dot. Examples of unqualified names are Date, today and <*>. Examples of qualified-names are Calendar.Date, Calendar.today and Monoid.<*>.

Qualifiers can be used to disambiguate. For example, there may be reason to use two different ops called union in the same context: one for set union, and one for bag (multiset) union. They could then more fully be called Set.union and Bag.union, respectively. Unlike in earlier versions of Specware, there is no rigid relationship between qualifiers and the unit-identifiers identifying specs. The author of a collection of specs may use the qualifier deemed most appropriate for any sort-name or op-name. For example, there could be a single spec dubbed SetsAndBags that introduces two new ops, one called Set.union and one called Bag.union. Generally, sorts and ops that "belong together" should receive the same qualifier. It is up to the author of the specs to determine what belongs together.

Sort-names and op-names are *introduced* in a declaration or definition, and may then be *employed* elsewhere in the same spec. Thus, all occurrences of a sort-name or op-name can be divided into "introductions" and "employs". The name as introduced in an introduction is the *full name* of the sort or op. If that name is unqualified, the full name is unqualified. If the name as introduced is qualified, then so is the full name.

For employs the rules are slightly different. First, if the name employed occurs just like that in an introduction, then it is the full name. Also, if the name employed is qualified, it is the full name. Otherwise, the name as employed may be unqualified shorthand for a qualified full name. For example, given an employ of the unqualified sort-name Date, possible qualified full names for it are Calendar.Date, DateAndTime.Date,

Diary. Date, and so on. But, of course, the full name must be one that is introduced in the spec. If there is precisely one qualified-name introduced whose last part is the same as the unqualified-name employed, then that name is the full name. Otherwise, sort information may be employed to disambiguate ("resolve overloading").

Here is an illustration of the various possibilities:

```
spec
  sort Apple
  sort Fruit.Apple
  sort Fruit.Pear
  sort Fruit.Date
  sort Calendar.Date
  sort Fruit.Basket = Apple * Pear * Date
endspec
```

In the definition of sort Fruit. Basket we have three unqualified employs of sort-names, viz. Apple, Pear and Date. The name Apple is introduced like that, so the employ Apple already uses the full name; it does not refer to Fruit. Apple. The name Pear is nowhere introduced just like that, so the employ must be shorthand for some qualified full name. There is only one applicable introduction, namely Fruit. Pear. Finally, for Date there are two candidates: Fruit. Date and Calendar. Date. This is ambiguous, and in fact an error. To correct the error, the employ of Date should be changed into either Fruit. Date or Calendar. Date, depending on the intention.

It is possible to give a qualification in one go to all unqualified-names introduced in a spec. If Q is a qualifier, and S is a term denoting a spec, then the term Q qualifying S denotes the same spec as S, except that each introduction of an unqualified-name N is replaced by an introduction of the qualified-name $Q \cdot N$. Employs that before referred to the unqualified introduction are also accordingly qualified, so that they now refer to the qualified introduction. For example, the value of

```
Company qualifying spec

sort Apple

sort Fruit.Apple

sort Fruit.Pear

sort Fruit.Basket = Apple * Pear

endspec

is the same as that of
```

sort Company.Apple

spec

```
sort Fruit.Apple
sort Fruit.Pear
sort Fruit.Basket = Company.Apple * Fruit.Pear
endspec

spec-qualification ::= qualifier qualifying spec-term

qualifier ::= word-symbol

qualifiable-name ::= unqualified-name | qualified-name

unqualified-name ::= name

qualified-name ::= qualifier . name

Sample spec-qualification:
    Weight qualifying /Units#Weights

Sample qualifiable-names:
    Key
    $
    Calendar.Date
    Monoid.<*>
```

Let R be the result of elaborating spec-term S. Then the elaboration of qualification Q qualifying S, where Q is a qualifier, is R with each unqualified sort-name or op-name N introduced there replaced by the qualified-name $Q \cdot N$. The same replacement applies to all uses of N identifying that introduced name.

For example, the elaboration of

```
Buffer qualifying spec
   op size : Nat
   axiom LargeSize is size >= 1024
   endspec

results in:
   spec
   op Buffer.size : Nat
   axiom LargeSize is Buffer.size >= 1024
```

```
endspec
```

Note that the claim-name LargeSize is unchanged. In later versions of Specware this may change, so that also unqualified claim-names get qualified.

2.3.2.3. Translations

```
spec-translation ::= translate spec-term by name-map
name-map ::= { [ name-map-item { , name-map-item }* ] }
name-map-item ::= sort-name-map-item | op-name-map-item
sort-name-map-item ::= [ sort ] qualifiable-name +-> qualifiable-name
op-name-map-item ::= [ op ] annotable-qualifiable-name +-> annotable-qualifiable-name
annotable-qualifiable-name ::= qualifiable-name [ : sort ]
Sample spec-translation:
    translate A by {Counter +-> Nat}
```

Let R be the result of elaborating spec-term S. Then the elaboration of translate S by $\{M_1 +-> N_1, \ldots, M_n +-> N_n\}$ is R with each occurrence of a qualifiable-name M, replaced by N.

For example, the elaboration of

```
translate spec
    sort E
    op i : E
endspec by {
    E +-> Counter,
    i +-> zero
}

results in:
    spec
    sort Counter
    op zero : Counter
```

endspec

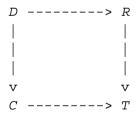

2.3.2.4. Substitutions

The elaboration of spec-substitution S[M] yields the spec T obtained as follows. Let spec R be the result of elaborating S, and morphism N that of M. Let specs D and C be the domain and codomain of N. First, remove from R all declarations of D, and subject the result to the effect of N, meaning that all name translations of N and all extensions with declarations are performed. Then add the declarations of C, but without duplications, i.e., as if C is imported. The result obtained is T.

Restriction. Spec D must be a "sub-spec" of spec R, meaning that each declaration of D is also a declaration of R.

Informally, T is to R as C is to D.

Except when R introduces, next to the sort-names and op-names it has in common with D, new sort-names or op-names that also occur in C, the result spec T is a categorical colimit of this pushout diagram:

Although isomorphic to the result that would be obtained by using a diagram-colimit, T is more "user-oriented" in two ways: the names in T are names from C, and axioms of D not repeated in C are not repeated here either.

For example, assume we have:

```
A = spec
  sort Counter
  op reset: Counter
  op tick : Counter -> Counter
  axiom Effect is
    fa (c : Counter) ~(tick c = c)
endspec
B = spec
  def reset = 0
  def tick c = c+1
endspec
M = morphism A -> B {Counter +-> Nat}
AA = spec
  import A
  sort Interval = {start: Counter, stop: Counter}
  op isEmptyInterval? : Interval -> Boolean
  def isEmptyInterval? \{start = x, stop = y\} = (x = y)
endspec
```

Then the result of AA[M] is the same as that of this spec:

```
spec
  import B
  sort Interval = {start: Nat, stop: Nat}
  op isEmptyInterval? : Interval -> Boolean
  def isEmptyInterval? {start = x, stop = y} = (x = y)
endspec
```

2.3.2.5. Diagram Colimits

```
diagram-colimit ::= colimit diagram-term
```

The result of elaborating a diagram-colimit is the spec which is the apex of the cocone forming the colimit in the category of specs and spec-morphisms. See further the Specware Tutorial.

2.3.2.6. Obligators

```
obligator ::= obligations unit-term
```

Restriction. The unit-term of an obligator must either be a spec-term or a morphism-term.

The result of elaborating an obligator is a spec containing the proof obligations engendered by the spec or morphism resulting from elaborating its unit-term. These proof obligations are expressed as conjectures; they can be discharged by proving them, using proof-terms. See further the Specware User Manual.

2.3.3. Morphisms

```
morphism-term ::=
    unit-identifier
    | spec-morphism

spec-morphism ::= morphism spec-term -> spec-term name-map
```

A morphism is a formal mapping between two closed specs that describes exactly how one is translated or extended into the other.

Restriction. When used as a morphism-term, the elaboration of a unit-identifier must yield a spec morphism.

Restriction ("proof obligations"). Given spec-morphism morphism $S \to T \{ M \}$, let S' be the result of elaborating translate S by $\{ M \}$, and let T' be the result of elaborating T. Then, first, each sort-name or op-name introduced in S' must also be introduced in T'. Further, no sort-name or op-name originating from a library spec may have been subject to translation. Finally, each axiom in S' must be a theorem that follows from the axioms of T'. Collectively, the axioms in S' are known as the *proof obligations* engendered by the morphism. They are the formal expression of the requirement that the step from S' to T' is a proper refinement.

2.3.4. Diagrams

```
diagram-term ::=
```

```
unit-identifier
| diagram-form

diagram-form ::= diagram { diagram-element { , diagram-element }* }

diagram-element ::=
    diagram-node
| diagram-edge

diagram-node ::= name +-> spec-term

diagram-edge ::= name : name -> name +-> morphism-term
```

Restriction. When used as a diagram-term, the elaboration of a unit-identifier must yield a diagram.

Restriction. In a diagram, the first name of each diagram-node and diagram-edge must be unique (i.e., not be used more than once in that diagram). Further, for each diagram-edge $E: ND \rightarrow NC +-> M$, there must be diagram-nodes ND +-> D and NC +-> C of the diagram such that, after elaboration, M is a morphism from D to C.

Sample diagram:

The result of elaborating a diagram-form is the categorical diagram whose nodes are labeled with the specs and whose edges are labeled with the morphisms that result from elaborating the corresponding spec-terms and morphism-terms.

2.3.5. Target Code Terms

```
target-code-term ::=
```

The elaboration of a target-code-term for a correct spec-term generates code in the language suggested by the target-language-name (currently only Common Lisp); see further the Specware User Manual.

2.3.6. Proof Terms

Restriction. The claim-names must occur as claim-names in the spec that results from elaborating the spec-term.

Sample proof-term:

The elaboration of a proof-term invokes the prover suggested by the prover-name (currently only SNARK). The property to be proved is the claim of the first claim-name; the claim-list lists the hypotheses (assumptions) that may be used in the

proof. The prover-options are prover-specific and are not further described here. For details, see the Specware User Manual.

2.4. Declarations

```
declaration ::=
      import-declaration
      sort-declaration
      op-declaration
      definition
definition ::=
      sort-definition
      op-definition
     | claim-definition
equals ::= is | =
Sample declarations:
    import Lookup
    sort Key
    op present : Database * Key -> Boolean
    sort Key = String
    def present(db, k) = embed? Some (lookup (db, k))
    axiom norm_idempotent is fa(x) norm (norm x) = norm x
```

2.4.1. Import-declarations

A spec may contain one or more import-declarations. On elaboration, these are "expanded". The effect is as if the bodies of these imported specs (themselves in elaborated form, which means that all import-declarations have been expanded, all translations performed and all shorthand employs of names have been resolved to full names, after which only declarations or definitions of sorts, ops and axioms are left) is inserted in place in the receiving spec.

For example, the result of

```
spec
   import spec
        sort A.Z
        op b : Nat -> Z
        end
   sort A.Z = String
   def b = toString
   endspec

is this "expanded" Spec:
```

```
spec
  sort A.Z
  op b : Nat -> A.Z
  sort A.Z = String
  def b = toString
endspec
```

For this to be correct, the imported specs must be correct by themselves; in addition, the result of expanding them in place must result in a correct spec.

There are a few restrictions, which are meant to catch unintentional naming mistakes. First, if two different imported **specs** each introduce a sort or **op** with the same (full) name, the introductions must be identical declarations or definitions, or one may be a declaration and the other a "compatible" definition. For example, given

```
S1 = spec op e : Integer end
S2 = spec op e : Char end
S3 = spec def e = 0 end
```

the specs S1 and S3 can be imported together, but all other combinations of two or more co-imported specs are incorrect. This restriction is in fact a special case of the general requirement that import expansion must result in a correct spec. Secondly, a sort-name introduced in any of the imported specs cannot be re-introduced in the receiving spec except for the case of an "imported" declaration together with a definition in the receiving spec. Similarly for op-names, with the addition that an op-definition in the receiving spec must be compatible with an op-declaration for the same name in an imported spec. The latter is again a special case of the general requirement that import expansion must result in a correct spec.

Chapter 2. Metaslang

What is specifically excluded by the above, is giving a definition of a sort or op in some spec, import it, and then redefining or declaring that sort or op with the same full name in the receiving spec.

```
import-declaration ::= import spec-term
Sample import-declarations
import Lookup
```

An import-declaration is contained in some spec-form, and to elaborate that spec-form the spec-term of the import-declaration is elaborated first, giving some spec S. The import-declaration has then the effect as if the declarations of the imported spec S are expanded in place. This cascades: if spec S imports S, and spec S imports S, then effectively spec S also imports S. An important difference with earlier versions of Specware than version S is that multiple imports of the same spec have the same effect as a single import.

If spec A is imported by B, each model of B is necessarily a model of A (after "forgetting" any names newly introduced by B). So A is then refined by B, and the morphism from A to B is known as the "import morphism". As it does not involve translation of sort-names or op-names, it can be denoted by morphism $A \rightarrow B$ {}.

2.4.2. Sort-declarations

```
sort-declaration ::= sort sort-name [ formal-sort-parameters ]

formal-sort-parameters ::= local-sort-variable | ( local-sort-variable-list )

local-sort-variable ::= name

local-sort-variable-list ::= local-sort-variable { , local-sort-variable }*

Restriction. Each local-sort-variable of the formal-sort-parameters must be a
```

Sample sort-declarations:

different name.

```
sort Date
sort Array a
```

```
sort Map(a, b)
```

Every sort-name used in a spec must be declared (in the same spec or in an imported spec, included the "built-in" specs that are always implicitly imported). A sort-name may have *sort parameters*. Given the example sort-declarations above, some valid sorts that can be used in this context are Array Date, Array (Array Date) and Map (Nat, Boolean).

In a model of the spec, a sort is assigned to each unparameterized sort-name, while an infinite *family* of sorts is assigned to parameterized sort-names "indexed" by tuples of sorts, that is, there is one family member, a sort, for each possible assignment of sorts to the local-sort-variables. So for the above example sort-declaration of Array one sort must be assigned to Array Nat, one to Array Boolean, one to Array (Array Date), and so on. These assigned sorts could all be the same sort, or perhaps all different, as long as the model respects sorting.

2.4.3. Sort-definitions

sort-definition ::= sort sort-name [formal-sort-parameters] equals sort Sample sort-definitions:

```
sort Date = {year : Nat, month : Nat, day : Nat}
sort Array a = List a
sort Map(a, b) = (Array (a * b) | key_uniq?)
```

In each model, the sort assigned to the **sort-name** must be the same as the right-hand-side **sort**. For parameterized sorts, this extends to all possible assignments of sorts to the **local-sort-variables**, taking the right-hand **sorts** as interpreted under each of these assignments. So, for the example, Map(Nat, Char) is the same sort as (Array (Nat * Char) | key_uniq?), and so on.

With *recursive* sort-definitions, there are additional requirements. For example, consider

```
sort Stack a =
    | Empty
    | Push {top : a, pop : Stack a}
```

Chapter 2. Metaslang

This means that for each sort a there is a value <code>Empty</code> of sort <code>Stack a</code>, and further a function <code>Push</code> that maps values of sort <code>{top:a,pop:Stack a}</code> to <code>Stack a</code>. Furthermore, the sort assigned to <code>Stack a</code> must be such that all its inhabitants can be constructed <code>exclusively</code> and <code>uniquely</code> in this way: there is one inhabitant <code>Empty</code>, and all others are the result of a <code>Push</code>. Finally -- this is the point -- the sort in the model must be such that its inhabitants can be constructed this way in <code>a finite number of steps</code>. So there can be no "bottom-less" stacks: deconstructing a stack using

is a procedure that is guaranteed to terminate, always resulting in true.

In general, sort-definitions generate implicit axioms, which for recursive definitions imply that the sort is not "larger" than necessary. In technical terms, in each model the sort is the least fixpoint of a recursive domain equation.

2.4.4. Op-declarations

```
op-declaration ::= op op-name [ fixity ] : sort-scheme

fixity ::= associativity priority

associativity ::= infix1 | infixr

priority ::= nat-literal

sort-scheme ::= [ sort-variable-binder ] sort

sort-variable-binder ::= fa ( local-sort-variable-list )

Sample op-declarations:
    op usage : String
    op o infixl 24 : fa(a,b,c) (b -> c) * (a -> b) -> a -> c
```

An op-declaration introduces an op-name with an associated sort. The sort can be "monomorphic", like String, or "polymorphic" (indicated by a sort-variable-binder). In the latter case, an indexed family of values is assigned to parameterized sort-names "indexed" by tuples of sorts, that is, there is one family member, a sorted value, for each possible assignment of sorts to the local-sort-variables of the sort-variable-binder, and the sort of that value is the result of the corresponding substitution of sorts for local-sort-variables on the polymorphic sort of the op. In the example above, the declaration of polymorphic o can be thought of as introducing a family of (fictitious) ops, one for each possible assignment to the local-sort-variables a, b and c:

```
O<sub>Nat,String,Char</sub> : (String -> Char) * (Nat -> String) -> Nat -> Char

O<sub>Nat,Nat,Boolean</sub> : (Nat -> Boolean) * (Nat -> Nat) -> Nat -> Boolean

O<sub>Char,Boolean,Nat</sub> : (Boolean -> Nat) * (Char -> Boolean) -> Char -> Nat
```

and so on. Any op-definition for o must be likewise accommodating.

Only binary ops (those having some sort $S * T \to U$) may be declared with a fixity. When declared with a fixity, the op-name may be used in infix notation, and then it is called an *infix operator*. For o above, this means that o(f, g) and f o g may be used, interchangeably, with no difference in meaning. If the associativity is infix1, the infix operator is called *left-associative*; otherwise, if the associativity is infixr, it is called *right-associative*. If the priority is priority N, the operator is said to have *priority* N. The nat-literal N stands for a natural number; if infix operator O1 has priority N1, and O2 has priority N2, with N1 < N2, we say that O1 has *lower priority* than O2, and that O2 has *higher priority* than (or *takes priority over*) O1. For the role of the associativity and priority, see further at *Infix-applications*.

2.4.5. Op-definitions

```
op-definition ::=
    def [ sort-variable-binder ] formal-expression [ : sort ] equals
        expression

formal-expression ::= op-name | formal-application

formal-application ::= formal-application-head formal-parameter

formal-application-head ::= op-name | formal-application
```

formal-parameter ::= closed-pattern

Sample op-definitions:

```
def usage = "Usage: Lookup key [database]"

def fa(a,b,c) o(f : b -> c, g: a -> b) : a -> c =
  fn (x : a) -> f(g x)

def o(f, g) x = f(g x)
```

Restriction. See the restriction under *Op-declarations* on redeclaring/redefining ops.

Note that a formal-expression always contains precisely one op-name, which is the op *being defined* by the op-definition. Note further that the formal-application of an op-definition always uses prefix notation, also for infix operators.

An op can be defined without having been declared. In that case the op-definition generates an implicit op-declaration for the op, as well as implicit sort-declarations for "place-holder" sorts needed for the op-declaration. For example, an undeclared op defined by

```
def f x y = (x, y x)
```

generates implicit declarations like:

```
sort s4771
sort s4772
op f : s4771 -> (s4771 -> s4772) -> (s4771 * s4772)
```

in which \$4771 and \$4772 are fresh names. Note that this is not polymorphic, but monomorphic with *unspecified* sorts. However, the further uses of f must uniquely determine sorts for the place-holders. In general, sorting information on ops may be omitted, but sufficient information must be supplied when used, so that all expressions can be assigned a sort in the context in which they occur while uniquely associating the ops with op-declarations or op-definitions. If two different associations both give sort-correct specs, the spec is ambiguous and incorrect.

As for op-definitions, the presence of a sort-variable-binder signals that the op being defined is polymorphic. Note that the optional sort annotation in an op-definition may not be a polymorphic sort-scheme, unlike for op-declarations. For example, the following is ungrammatical:

```
def o : fa(a,b,c) (b -> c) * (a -> b) -> a -> c =
```

$$fn (f, g) -> fn (x) -> f(g x)$$

The presumably intended effect is achieved by

```
def fa(a,b,c) o : (b \rightarrow c) * (a \rightarrow b) \rightarrow a \rightarrow c =
fn (f, g) \rightarrow fn (x) \rightarrow f(g x)
```

In a model of the spec, an indexed family of sorted values is assigned to a polymorphic op, with one family member for each possible assignment of sorts to the local-sort-variables of the sort-variable-binder, and the sort of that value is the result of the corresponding sort-instantiation for the polymorphic sort of the op. Thus, we can reduce the meaning of a polymorphic op-definition to a family of (fictitious) monomorphic op-definitions.

An op-definition with formal-prefix-application

$$def H P = E$$

in which H is a formal-application-head, P is a formal-parameter and E an expression, is equivalent to the op-definition

$$def H = fn P \rightarrow E$$

For example,

$$def o (f, g) x = f(g x)$$

is equivalent to

$$def o (f, g) = fn x \rightarrow f(g x)$$

which in turn is equivalent to

$$def o = fn (f, q) \rightarrow fn x \rightarrow f(q x)$$

By this deparameterizing transformation for each formal-parameter, an equivalent unparameterized op-definition is reached. The semantics is described in terms of such op-definitions.

In each model, the sorted value assigned to the op being defined must be the same as the value of the right-hand-side expression. For polymorphic op-definitions, this extends to all possible assignments of sorts to the local-sort-variables.

An op-definition can be thought of as a special notation for an axiom. For example,

```
def fa(a) double (x : a) = (x, x)
```

can be thought of as standing for:

```
op double : fa(a) a -> a * a
axiom double_def is
  sort fa(a) fa(x : a) double x = (x, x)
```

In fact, Specware generates such axioms for use by provers. But in the case of recursive definitions, this form of axiomatization does not adequately capture the meaning. For example,

```
def f (n : Nat) : Nat = 0 * f n
```

is an improper definition, while

```
axiom f_def is fa(n : Nat) f n = 0 * f n
```

characterizes the function that maps every natural number to 0. The issue is the following. Values in models can not be <code>undefined</code> and functions assigned to <code>ops</code> must be <code>total</code>. But in assigning a meaning to a recursive <code>op-definition</code>, we -- temporarily -- allow <code>undefined</code> and partial functions (functions that are not everywhere defined on their domain sort) to be assigned to recursively defined <code>ops</code>. In the thus extended class of models, the recursive <code>ops</code> must be the least-defined solution to the "axiomatic" equation (the least fixpoint as in domain theory), given the assignment to the other <code>ops</code>. For the example of <code>f</code> above this results in the everywhere undefined function, since 0 times <code>undefined</code> is <code>undefined</code>. If the solution results in an undefined value or a function that is not total (or for higher-order functions, functions that may return non-total functions, and so on), the <code>op-definition</code> is improper. Specware 4.0 does not attempt to detect this condition or generate proof obligations for showing its absence.

Functions that are determined to be the value of an expression, but that are not assigned to ops, need not be total, but the context must enforce that the function can not be applied to values for which it is undefined. Otherwise, the spec is incorrect.

2.4.6. Claim-definitions

```
claim-definition ::= claim-kind claim-name equals claim
claim-kind ::= axiom | theorem | conjecture
```

```
claim-name ::= name

claim ::= [ sort-quantification ] expression

sort-quantification ::= sort sort-variable-binder
```

Sample claim-definitions:

```
axiom norm_idempotent is
  norm o norm = norm

theorem o_assoc is
  sort fa(a,b,c,d) fa(f : c -> d, g : b -> c, h : a -> b)
    f o (g o h) = (f o g) o h

conjecture pivot_hold is
  let p = pivot hold in
    fa (n : {n : Nat | n < p}) ~(hold n = hold p)</pre>
```

Restriction. The sort of the claim must be Boolean.

When a sort-quantification is present, the claim is polymorphic. The claim may be thought of as standing for an infinite family of monomorphic claims, one for each possible assignment of sorts to the local-sort-variables.

The claim-kind theorem should only be used for claims that have actually been proved to follow from the (explicit or implicit) axioms. In other words, giving them axiom status should not change the class of models. Theorems can be used by provers.

Conjectures are meant to represent proof obligations that should eventually attain theoremhood. Like theorems, they can be used by provers.

The Specware system passes on the claim-name of the claim-definition with the claim for purposes of identification. Both may be transformed to fit the requirements of the prover, and appear differently there. Not all claims can be faithfully represented in all provers, and even when they can, the logic of the prover may not be up to dealing with them.

Remark. It is a common mistake to omit the part "claim-name equals" from a claim-definition. A defensive style against this mistake is to have the claim always start on a new text line. This is additionally recommended because it may become required in future revisions of Metaslang.

2.5. Sorts

```
sort ::=
       sort-sum
     sort-arrow
     | slack-sort
slack-sort ::=
       sort-product
     | tight-sort
tight-sort ::=
       sort-instantiation
     | closed-sort
closed-sort ::=
       sort-name
       local-sort-variable
       sort-record
       sort-restriction
     sort-comprehension
     sort-quotient
     ( sort )
```

(The distinctions "slack-", "tight-" and "closed-" before "sort" have no semantic significance. The distinction merely serves the purpose of diminishing the need for parenthesizing in order to avoid grammatical ambiguities.)

Sample sorts:

```
| Point XYpos | Line XYpos * XYpos

List String * Nat -> Option String

a * Order a * a

PartialFunction (Key, Value)

Key

a

{center : XYpos, radius : Length}

(Nat | even)

{k : Key | present (db, k)}

Nat / (fn (m, n) -> m rem 3 = n rem 3)

(Nat * Nat)
```

The meaning of a parenthesized sort (S) is the same as that of the enclosed sort S.

The various other kinds of sorts not defined here are described each in their following respective sections, with the exception of local-sort-variable, whose (lack of) meaning as a sort is described below.

Restriction. A local-sort-variable may only be used as a sort if it occurs in the scope of a formal-sort-parameters or sort-variable-binder in which it is introduced.

Disambiguation. A single name used as a sort is a local-sort-variable when it occurs in the scope of a formal-sort-parameters or sort-variable-binder in which it is introduced, and then it identifies the textually most recent introduction. Otherwise, the name is a sort-name.

A local-sort-variable used as a sort has no meaning by itself, and where relevant to the semantics is either "indexed away" (for parameterized sorts) or "instantiated away" (when introduced in a formal-sort-parameters or sort-variable-binder) before a meaning is ascribed to the construct in which it occurs. Textually, it has a scope just like a plain local-variable.

2.5.1. Sort-sums

Restriction. The constructors of a sort-sum must all be different names.

The ordering of the sort-summands has no significance: | Zero | Succ Peano denotes the same "sum sort" as | Succ Peano | Zero.

A sort-sum denotes a *sum sort*, which is a sort that is inhabited by "tagged values". A tagged value is a pair (C, v), in which C is a constructor and v is a sorted value.

A sort-sum introduces a number of embedders, one for each sort-summand. In the discussion, we omit the optional embed keyword of the embedders. The embedders are similar to ops, and are explained as if they were ops, but note the Restriction specified under *Structors*.

Chapter 2. Metaslang

For a sort-sum SS with sort-summand CS, in which C is a constructor and S a sort, the corresponding pseudo-op introduced is sorted as follows:

```
op C : S \rightarrow SS
```

It maps a value v of sort S to the tagged value (C, v). If the sort-summand is a single parameter-less constructor (the slack-sort is missing), the pseudo-op introduced is sorted as follows:

```
op C : SS
```

It denotes the tagged value (C, ()), in which () is the inhabitant of the unit sort (see under *Sort-records*).

The sum sort denoted by the **sort-sum** then consists of the union of the ranges (for parameter-less constructors the values) of the pseudo-**ops** for all constructors.

The embedders are individually, jointly and severally *injective*, and jointly *surjective*.

This means, first, that for any pair of constructors C1 and C2 of any sort-sum, and for any pair of values v1 and v2 of the appropriate sort (to be omitted for parameter-less constructors), the value of C1 v1 is only equal to C2 v2 when C1 and C2 are the same constructor of the same sum sort, and v1 and v2 (which then are either both absent, or else must have the same sort) are both absent or are the same value. In other words, whenever the constructors are different, or are from different sort-sums, or the values are different, the results are different. (The fact that synonymous constructors of different sorts yield different values already follows from the fact that values in the models are sorted.)

Secondly, for any value u of any sum sort, there is a **constructor** C of that sum sort and a value v of the appropriate sort (to be omitted for parameter-less **constructors**), such that the value of C v is u. In other words, all values of a sum sort can be constructed with an **embedder**.

For example, consider

This means that there is a value Zero of sort Peano, and further a function Succ that maps values of sort Peano to sort Peano. Then Zero and Succ n are guaranteed to be

different, and each value of sort Peano is either Zero: Peano, or expressible in the form Succ (n: Peano) for a suitable expression n. The expressions Zero: Peano and Zero: Unique denote different, entirely unrelated, values. (Note that Unique is not a subsort of Peano. Subsorts of a sort can only be made with a Sort-restriction, for instance as in (Peano | embed? Zero).) For recursively defined sort-sums, see also the discussion under Sort-definitions.

Note. Although the sum sorts | Mono and | Mono () have exactly the same set of inhabitants when considered as unsorted values, these two sorts are different, and the pseudo-ops they introduce have different sorts, only the second of which is a function sort:

```
Mono : | Mono

Mono : () -> | Mono ()
```

2.5.2. Sort-arrows

```
sort-arrow ::= arrow-source -> sort
arrow-source ::= sort-sum | slack-sort
Sample sort-arrow:
    (a -> b) * b -> List a -> List b
```

In this example, the arrow-source is (a -> b) * b, and the (target) sort List a -> List b.

The function sort $S \to T$ is inhabited by precisely all partial or total functions from S to T. That is, function f has sort f if, and only if, for each value f sort f such that the value of f is defined, that value has sort f. Functions can be constructed with lambda-forms, and be used in applications.

In considering whether two functions (of the same sort) are equal, only the meaning on the domain sort is relevant. Whether a function is undefined outside its domain sort, or might return some value of some sort, is immaterial to the semantics of Metaslang. (For a sort-correct Spec, the difference is unobservable.)

2.5.3. Sort-products

```
sort-product ::= tight-sort * tight-sort { * tight-sort }*
Sample sort-product:
    (a -> b) * b * List a
```

Note that a sort-product contains at least two constituent tight-sorts.

A sort-product denotes a *product sort* that has at least two "component sorts", represented by its tight-sorts. The ordering of the component sorts is significant: unless S and T are the same sort, the product sort S * T is different from the sort T * S. Further, the three sorts (S * T) * U, S * (T * U) and S * T * U are all different; the first two have two component sorts, while the last one has three. The inhabitants of the product sort $S_1 * S_2 * ... * S_n$ are precisely all n-tuples $(v_1, v_2, ..., v_n)$, where each v_i has sort s_i , for i = 1, 2, ..., n. Values of a product sort can be constructed with tuple-displays, and component values can be extracted with tuple-patterns as well as with projectors.

2.5.4. Sort-instantiations

Restriction. The sort-name must have been declared or defined as a parameterized sort (see *Sort-declarations*), and the number of sorts in the actual-sort-parameters must match the number of local-sort-variables in the formal-sort-parameters of the sort-declaration and/or sort-definition.

The sort represented by a sort-instantiation is the sort assigned for the combination of sorts of the actual-sort-parameters in the indexed family of sorts for the sort-name of the sort-instantiation.

2.5.5. Sort-names

```
sort-name ::= qualifiable-name
Sample sort-names:
    Key
    Calendar.Date
```

Restriction. At the spec level, a sort-name may only be used if there is a sort-declaration and/or sort-definition for it in the current spec or in some spec that is imported (directly or indirectly) in the current spec. If there is a unique qualified-name for a given unqualified ending, the qualification may be omitted for a sort-name used as a sort.

The sort of a **sort-name** is the sort assigned to it in the model. (In this case, the context can not have superseded the original assignment.)

2.5.6. Sort-records

```
sort-record ::= { [ field-sorter-list ] } | ( )
field-sorter-list ::= field-sorter { , field-sorter }*
field-sorter ::= field-name : sort
field-name ::= name
Sample sort-record:
    {center : XYpos, radius : Length}
```

Restriction. The field-names of a sort-record must all be different.

Note that a sort-record contains either no constituent field-sorters, or else at least two.

A sort-record is like a sort-product, except that the components, called "fields", are identified by name instead of by position. The ordering of the field-sorters has no significance: {center: XYpos, radius: Length} denotes the same record sort as {radius: Length, center: XYpos}. Therefore we assume in the following, without loss of generality, that the fields are ordered lexicographically according to their field-names (as in a dictionary: a comes before ab comes before b) using some

Chapter 2. Metaslang

fixed collating order for all marks that may comprise a name. Then each field of a record sort with n fields has a *position* in the range 1 to n. The inhabitants of the record sort $\{F_1: S_1, F_2: S_2, \ldots, F_n: S_n\}$ are precisely all n-tuples (v_1, v_2, \ldots, v_n) , where each v_i has sort S_i , for $i=1,2,\ldots,n$. The field-names of that record sort are the field-names F_1,\ldots,F_n , and, given the lexicographic ordering, field-name F_i selects position i, for $i=1,2,\ldots,n$. Values of a record sort can be constructed with record-displays, and field values can be extracted with record-patterns and (as for product sorts) with projectors.

For the **sort-record** {}, which may be equivalently written as (), the record sort it denotes has zero components, and therefore no **field-names**. This zero-component sort has precisely one inhabitant, and is called the *unit sort*. The unit sort may equally well be considered a product sort, and is the only sort that is both a product and a record sort.

2.5.7. Sort-restrictions

```
sort-restriction ::= ( slack-sort | expression )
```

Sample sort-restriction:

```
(Nat | even)
```

Restriction. In a sort-restriction $(S \mid P)$, the expression P must be a predicate on the sort S, that is, P must be a function of sort S -> Boolean.

Note that the parentheses in $(S \mid P)$ are mandatory.

The inhabitants of sort-restriction $(S \mid P)$ are precisely the inhabitants of sort S that satisfy the predicate P, that is, they are those values v for which the value of P v is true.

If P1 and P2 are the same function, then $(S \mid P1)$ and $(S \mid P2)$ are equivalent, that is, they denote the same sort.

The sort $(S \mid P)$ is called a *subsort* of *supersort* S. Values can be shuttled between a subsort and its supersort and vice versa with relaxators and restrict-expressions; see also *Relax-patterns*.

Metaslang does not require the explicit use of a relaxator to relax an expression from a subsort to its supersort if the context requires the latter. Implicit relaxation will take place when needed. For example, in the expression ~1 the nat-literal 1 of sort Nat is implicitly relaxed to sort Integer to accommodate the unary negation operator ~, which has sort Integer -> Integer.

Likewise, Metaslang does not require the explicit use of a restrict-expression to restrict an expression from a sort to a subsort if the context requires the latter. Implicit restriction will take place when needed. For example, in the expression 7 div 2 the nat-literal 2 of sort Nat is implicitly restricted to sort PosNat, a subsort of Nat, to accommodate the division operator div, whose second argument has sort PosNat. But note that implicit restriction engenders the same proof obligation as results when using an explicit restrict-expression.

2.5.8. Sort-comprehensions

```
sort-comprehension := \{ annotated-pattern \mid expression \}
```

Sample sort-comprehension:

```
{n : Nat | even n}
```

Restriction. In a sort-comprehension $\{P : S \mid E\}$, the expression E must have sort Boolean.

Sort-comprehensions provide an alternative notation for sort-restrictions that is akin to the common mathematical notation for set comprehensions. The meaning of sort-comprehension $\{P: S \mid E\}$ is the same as that of the sort-restriction $(S \mid fn \mid P \mid > E)$. So the meaning of the example sort-comprehension above is (Nat $\mid fn \mid n \mid > even \mid n$).

2.5.9. Sort-quotients

```
sort-quotient ::= closed-sort / closed-expression
```

Sample sort-quotient:

```
Nat / (fn (m, n) -> m rem 3 = n rem 3)
```

Restriction. In a sort-quotient $S \neq Q$, the expression Q must be a (binary) predicate on the sort S * S that is an equivalence relation, as explained below.

Equivalence relation. Call two values x and y of sort S "Q-related" if (x, y) satisfies Q. Then Q is an *equivalence relation* if, for all values x, y and z of sort S, x is Q-related to itself, y is Q-related to x whenever x is Q-related to y, and x is Q-related to z

Chapter 2. Metaslang

whenever x is Q-related to y and y is Q-related to z. The equivalence relation Q then partitions the inhabitants of S into *equivalence classes*, being the maximal subsets of S containing mutually Q-related members. These equivalence classes will be called "Q-equivalence classes".

The inhabitants of the *quotient sort* S / Q are precisely the Q-equivalence classes into which the inhabitants of S are partitioned by Q. For the example above, there are three equivalence classes of natural numbers leaving the same remainder on division by 3: the sets $\{0, 3, 6, ...\}$, $\{1, 4, 7, ...\}$ and $\{2, 5, 8, ...\}$, and so the quotient sort has three inhabitants.

2.6. Expressions

```
expression ::=
        lambda-form
       case-expression
       let-expression
       if-expression
       quantification
       annotated-expression
       tight-expression
tight-expression ::=
        application
       restrict-expression
       closed-expression
closed-expression ::=
        op-name
       local-variable
       literal
       field-selection
       tuple-display
       record-display
       sequential-expression
       list-display
       structor
        ( expression )
```

(The distinctions tight- and closed- for expressions lack semantic significance, and merely serve the purpose of avoiding grammatical ambiguities.)

Sample expressions:

```
fn (s : String) -> s ^ "."
case z of \{re = x, im = y\} \rightarrow \{re = x, im = \sim y\}
let x = x + 1 in f(x, x)
if x \le y then x else y
fa(x,y) (x \le y) \le ((x \le y) \text{ or } (x = y))
f(x, x)
[]: List Arg
<=>
x
3260
z.re
("George", Poodle : Dog, 10)
{name = "George", kind = Poodle : Dog, age = 10}
(writeLine "key not found"; embed Missing)
["Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat"]
project 2
(n + 1)
```

Restriction. Like all polymorphic or sort-ambiguous constructs, an expression can only be used in a context if its sort can be inferred uniquely, given the expression and the context. This restriction will not be repeated for the various kinds of expressions defined in the following subsections.

The meaning of a parenthesized expression (E) is the same as that of the enclosed expression E.

The various other kinds of expressions not defined here are described each in their following respective sections, with the exception of local-variable, whose meaning as an expression is described below.

Restriction. A local-variable may only be used as an expression if it occurs in the scope of the local-variable-list of a quantification or of a variable-pattern in which it is introduced.

Disambiguation. A single name used as an expression is a local-variable when it occurs in the scope of a local-variable-list or variable-pattern in which a synonymous local-variable is introduced, and then it identifies the textually most recent introduction. Otherwise, the name is an op-name or an embedder; for the disambiguation between the latter two, see *Embedders*.

A local-variable used as an expression has the sorted value assigned to it in the environment.

2.6.1. Lambda-forms

```
lambda-form ::= fn match
```

Sample lambda-form:

```
fn (s : String) -> s ^ "."
```

The value of a lambda-form is a partial or total function. If the value determined for a lambda-form as described below is not a total function, the context must enforce that the function can not be applied to values for which it is undefined. Otherwise, the spec is incorrect. Specware 4.0 does not attempt to generate proof obligations for establishing this.

The sort of a lambda-form is that of its match. The meaning of a given lambda-form of sort $S \to T$ is the function f mapping each inhabitant f of f to a value f of sort f, where f is the return value of f for the match of the lambda-form. If the match accepts each f of sort f (for acceptance and return value, see the section on f is total; otherwise it is partial, and undefined for those values f rejected.

In case of a recursive definition, the above procedure may fail to determine a value for y, in which case function f is not total, but undefined for x.

2.6.2. Case-expressions

```
case-expression ::= case expression of match
```

Sample case-expressions:

The value of a case-expression case E of M is the same as that of the application (fn M) (E).

2.6.3. Let-expressions

In the case of a recless-let-binding (recless = recursion-less), the value of the let-expression let P = A in E is the same as that of the application (fn $P \rightarrow E$) (A). For the first example above, this amounts to f(x + e, x + e). Note that x = x + e is not interpreted as a recursive definition.

In case of a rec-let-binding-sequence (rec = recursive), the rec-let-bindings have the role of "local" op-definitions; that is, they are treated exactly like op-definitions except that they are interpreted in the local environment instead of the global model. For the second example above, this amounts to (x + e) + e. (If e is a local-variable in this scope, the definition of f can not be "promoted" to an op-definition, which would be outside the scope binding e.) A spec with rec-let-bindings can be transformed into one without such by creating op-definitions for each rec-let-binding that take additional arguments, one for each of the local-variables referenced. For the example, in which f references local-variable e, the op-definition for the "extended" op f^+ would be f^+ e f e

Note that the first occurrence of x in the above example of a rec-let-binding is a variable-pattern and the second-occurrence is in its scope; the third and last occurrence of x, however, is outside the scope of the first x and identifies an op or local-variable x introduced elsewhere. So, without change in meaning, the rec-let-binding can be changed to:

```
let def f xena = xena + e in f (f x)
```

2.6.4. If-expressions

if-expression ::= if expression then expression else expression
Sample if-expression:

```
if x <= y then x else y
```

The value of an if-expression if B then T else F is the same as that of the case-expression case B of true \rightarrow (T) | false \rightarrow (F).

2.6.5. Quantifications

```
quantification ::= quantifier ( local-variable-list ) expression  
quantifier ::= fa \mid ex  
local-variable-list ::= annotable-variable { , annotable-variable }*  
annotable-variable ::= local-variable [ : sort ]  
local-variable ::= name  
Sample quantifications:  
fa(x) \text{ norm (norm } x) = norm x 
ex(e : M) fa(x : M) x <*> e = x & e <*> x = x
```

Restriction. Each local-variable of the local-variable-list must be a different name.

Quantifications are non-constructive, even when the domain sort is finitely enumerable. The main uses are in sort-restrictions and sort-comprehensions, and claims. The sort of a quantification is Boolean. There are two kinds of quantifications: fa-quantifications (or "universal quantifications"; fa = for all), and ex-quantifications (or "existential quantifications"; ex = there exists).

The value of a fa-quantification fa V E, in which V is a local-variable-list and E is an expression, is determined as follows. Let M be the match $V \rightarrow E$. If M has return value true for each value x in its domain (note that rejection cannot happen here), the value of the quantification is true; otherwise it is false.

The value of an ex-quantification ex V E is the same as that of the fa-quantification \sim (fa $V \sim (E)$).

Note that fa and ex must be followed by an opening parenthesis (. So fa x (x = x), for example, is ungrammatical.

2.6.6. Annotated-expressions

```
annotated-expression ::= tight-expression : sort
```

Restriction. In an annotated-expression E: S, the expression E must have sort S. Sample annotated-expression:

```
[]: List Arg
Positive: Sign
```

The value of an annotated-expression E : S is the value of E.

The sort of some expressions is polymorphic. For example, for any sort T, [] denotes the empty list of sort List T. Likewise, constructors of parameterized sum sorts can be polymorphic, as the constructor None of

```
sort Option a = | Some a | None
```

Further, overloaded constructors have an ambiguous sort. By annotating such polymorphic or sort-ambiguous expressions with a sort, their sort can be disambiguated, which is required unless an unambiguous sort can already be inferred from the context. Annotation, even when redundant, can further help to increase clarity.

2.6.7. Applications

```
application ::= prefix-application | infix-application prefix-application ::= application-head actual-parameter
```

Chapter 2. Metaslang

```
application-head ::= closed-expression | prefix-application
actual-parameter ::= closed-expression
infix-application ::= operand op-name operand
operand ::= tight-expression
```

Sample applications:

```
f(x, x)
f x (g y)
x + 1
```

Restriction. The op-name of an infix operator, whether qualified or unqualified, may not be used without more as an actual-parameter or operand. To use an infix op as an actual-parameter or operand, it must be enclosed in parentheses, as for example in the prefix-applications fold1 (+) 0 and fold1 (*) 1 or the infix-application (<) o ival. Note the space between "(" and "*", since without space "(*" signals the start of a comment.

Restriction. The op-name of an infix-application must have been declared as an infix operator (see under *Op-declarations*).

Disambiguation. An infix-application P M O N R, in which P, O and R are operands and M and N are infix operators, is interpreted as either (P M O) N R or P M (Q N R). The choice is made as follows. If M has higher priority than N, or the priorities are the same but M is left-associative, the interpretation is $(P \ M \ Q) \ N \ R$. In all other cases the interpretation is P M (Q N R). For example, given

```
op @ infixl 10: Nat * Nat -> Nat
op $ infixr 20: Nat * Nat -> Nat
```

the following interpretations hold:

```
1 \ \$ \ 2 \ @ \ 3 = (1 \ \$ \ 2) \ @ \ 3
1 @ 2 @ 3 = (1 @ 2) @ 3
1 @ 2 $ 3 = 1 @ (2 $ 3)
1 \ \$ \ 2 \ \$ \ 3 = 1 \ \$ \ (2 \ \$ \ 3)
```

Note that no sort information is used in the disambiguation. If (1 @ 2) \$ 3 is sort-correct but 1 @ (2 \$ 3) is not, the formula 1 @ 2 \$ 3 is sort-incorrect, since its interpretation is.

Restriction. In an application H P, in which H is an application-head and P an actual-parameter, the sort of P must be some function sort $S \rightarrow T$, and then H must have the domain sort S. The sort of the whole application is then T.

The value of application H P is the value returned by function H for the argument value P. (Since infix-applications may always be rewritten equivalently as prefix-applications, only the semantics for prefix-applications is given explicitly.)

2.6.8. Restrict-expressions

restrict-expression ::= restrict closed-expression closed-expression

Sample restrict-expression:

```
restrict posNat? (n+1)
```

Restriction. In a restrict-expression restrict P E the expression P must have function sort $S \rightarrow Boolean$ and the expression E must have sort S for some S.

The sort of a restrict-expression restrict PE, where P has sort $S \rightarrow$ Boolean, is the sort $(S \mid P)$.

A restrict-expression restrict PE is a convenient notation for the let-expression let relax PV = E in V, where V is some unique fresh name, that is, it is any name that does not already occur in the Spec, directly or indirectly through an import.

The use of this **restrict-expression** engenders a proof obligation that the value of E satisfies predicate P.

For example, assuming the definitions from the Base Library for Nat, the restrict-expression restrict posNat? (n+1) has sort PosNat. The proof obligation here is that, in the context, (n+1) > 0.

The purpose of restrict-expressions is to make it explicit that an expression whose a-priori sort is some supersort S actually is guaranteed (or required) to have subsort ($S \mid P$). Note, however, that Metaslang does not require the explicit use of a restrict-expression to restrict an expression from a sort to a subsort if the context requires the latter. Implicit restriction will take place when needed. For example, in the expression 7 div 2 the nat-literal 2 of sort Nat is implicitly restricted to sort PosNat, a subsort of Nat, to accommodate the division operator div, whose second argument has sort PosNat. But note that implicit restriction engenders the same proof obligation as results when using an explicit restrict-expression.

2.6.9. Op-names

```
op-name ::= qualifiable-name
Sample op-names:
    length
    >=
    DB_LOOKUP.Lookup
```

Restriction. An op-name may only be used if there is an op-declaration and/or op-definition for it in the current spec or in some spec that is imported (directly or indirectly) in the current spec. If there is a unique qualified-name for a given unqualified ending that is sort-correct in the context, the qualification may be omitted for an op-name used as an expression. So overloaded ops may only be used as such when their sort can be disambiguated in the context.

The value of an **op-name** is the value assigned to it in the model. (In this case, the context can not have superseded the original assignment.)

2.6.10. Literals

```
literal ::=
boolean-literal
nat-literal
char-literal
string-literal
```

Sample literals:

```
true
3260
#z
"On/Off switch"
```

Restriction: No whitespace is allowed anywhere inside any kind of literal, except for "significant" whitespace in string-literals, as explained there.

Literals provide denotations for the inhabitants of the "built-in" sorts Boolean, Nat, Char and String. The value of a literal is independent of the environment.

(There are no literals for the built-in sort Integer. For nonnegative integers, a nat-literal can be used. For negative integers, apply the built-in $op \sim$, which negates an integer, or use the built-in infix operator -: both ~ 1 and 0 - 1 denote the negative integer -1.)

2.6.10.1. Boolean-literals

```
boolean-literal ::= true | false
Sample boolean-literals:
    true
    false
```

The sort Boolean has precisely two inhabitants, the values of true and false.

Note that true and false are not constructors. So embed true is ungrammatical.

2.6.10.2. Nat-literals

```
nat-literal ::= decimal-digit { decimal-digit }*

Sample nat-literals:

3260
007
```

The sort Nat is, by definition, the subsort of Integer restricted to the nonnegative integers $0, 1, 2, \ldots$, which we identify with the natural numbers. The value of a nat-literal is the natural number of which it is a decimal representation; for example, the nat-literal 3260 denotes the natural number 3260. Leading decimal-digits 0 have no significance: both 007 and 7 denote the number 7.

2.6.10.3. Char-literals

```
char-literal ::= #char-literal-glyph
char-literal-glyph ::= char-glyph | "
```

Chapter 2. Metaslang

Sample char-literals:

```
#z
#\x7a
```

The sort Char is inhabited by the 256 8-bit *characters* occupying decimal positions 0 through 255 (hexadecimal positions 00 through FF) in the ISO 8859-1 code table. The first 128 characters of that code table are the traditional ASCII characters (ISO 646). (Depending on the operating environment, in particular the second set of 128 characters -- those with "the high bit set" -- may print or otherwise be visually presented differently than intended by the ISO 8859-1 code.) The value of a char-literal is a character of sort Char.

The value of a char-literal #G, where G is a char-glyph, is the character denoted by G. For example, #z is the character that prints as z. The two-mark char-literal # provides a variant notation of the three-mark char-literal # and yields the character # (decimal position 34).

Each one-mark char-glyph C denotes the character that "prints" as C. The two-mark char-glyph $\$ denotes the character $\$ (decimal position 92), and the two-mark char-glyph $\$ denotes the character $\$ (decimal position 34).

Notations are provided for denoting eight "non-printing" characters, which, with the exception of the first, are meant to regulate lay-out in printing; the actual effect may depend on the operating environment:

glyph	decimal	name
\a	7	bell
\a \b	8	backspace
\t	9	horizontal tab
\n	10	newline
\v	11	vertical tab
\f	12	form feed
\r	13	return
\s	32	space

Finally, every character can be obtained using the hexadecimal representation of its position. The four-mark char-glyph $\xspace x H_1 H_0$ denotes the character with hexadecimal position $H_1 H_0$, which is decimal position 16 times the decimal value of hexadecimal-digit H_1 plus the decimal value of hexadecimal-digit H_0 , where the decimal value of the digits 0 through 9 is conventional, while the six extra digits A through F correspond to 10 through 15. The case (lower or upper) of the six extra digits is not significant. For example, $\xspace x 7A$ or equivalently $\xspace x 7a$ has decimal position 16 times 7 plus $\xspace 10 = 122$, and either version denotes the character z. The "null" character can be obtained by using $\xspace x 00$.

2.6.10.4. String-literals

```
string-literal ::= " string-body "
string-body ::= { string-literal-glyph }*
string-literal-glyph ::= char-glyph | significant-whitespace
significant-whitespace ::= space | tab | newline
```

The presentation of a significant-whitespace is the whitespace suggested by the name (space, tab or newline).

Sample string-literals:

```
""
"see page"
"see\spage"
```

```
"the symbol ' is a single quote"
"the symbol \" is a double quote"
```

The sort String is inhabited by the *strings*, which are (possibly empty) sequences of characters. The sort String is primitive; it is a different sort than the isomorphic sort List Char, and the list operations can not be directly applied to strings.

The value of a string-literal is the sequence of characters denoted by the string-literal-glyphs comprising its string-body, where the value of a significant-whitespace is the whitespace character suggested by the name (space, horizontal tab or newline). For example, the string-literal "seepage" is different from "see page"; the latter denotes an eight-character string of which the fourth character is a space. The space can be made explicit by using the char-glyph \s.

When a double-quote character " is needed in a string, it must be escaped, as in " $[6'2\]$ ", which would print like this: $[6'2\]$ ".

2.6.11. Field-selections

```
field-selection ::= closed-expression . field-selector field-selector ::= nat-literal | field-name
```

Disambiguation. A closed-expression of the form M.N, in which M is a word-symbol and N is a name, is interpreted as an op-name if M.N occurs as the op-name of an op-declaration or op-definition in the spec in which it occurs or in the set of names imported from another spec through an import-declaration. Otherwise, M.N is interpreted as a field-selection. (The effect of a field-selection can always be obtained with a projector.)

Sample field-selections:

```
triple.2 z.re
```

A field-selection E. F is a convenient notation for the equivalent expression (project F E). (See under *Projectors*.)

2.6.12. Tuple-displays

```
tuple-display ::= ( tuple-display-body )
tuple-display-body ::= [ expression , expression { , expression }* ]
Sample tuple-display:
    ("George", Poodle : Dog, 10)
```

Note that a tuple-display-body contains either no expressions, or else at least two.

The value of a tuple-display whose tuple-display-body is not empty, is the tuple whose components are the respective values of the expressions of the tuple-display-body, taken in textual order. The sort of that tuple is the "product" of the corresponding sorts of the components. The value of () is the empty tuple, which is the sole inhabitant of the unit sort (). (The fact that the notation () does double duty, for a sort and as an expression, creates no ambiguity. Note also that -- unlike the empty list-display [] -- the expression () is monomorphic, so there is no need to ever annotate it with a sort.)

2.6.13. Record-displays

The value of a record-display is the record whose components are the respective values of the expressions of the record-display-body, taken in the lexicographic order of the field-names, as discussed under *Sort-records*. The sort of that record is the record sort with the same set of field-names, where the sort for each field-name F is the sort of the corresponding sort of the component selected by F in the record. The value of $\{\}$ is the empty tuple, which is the sole inhabitant of the unit sort (). (For expressions as well as for sorts, the notations $\{\}$ and () are fully interchangeable.)

2.6.14. Sequential-expressions

```
sequential-expression ::= ( open-sequential-expression )
open-sequential-expression ::= void-expression ; sequential-tail
void-expression ::= expression
sequential-tail ::= expression | open-sequential-expression
Sample sequential-expression:
   (writeLine "key not found"; embed Missing)
```

A sequential-expression (V; T) is equivalent to the let-expression let $_ = V \text{ in } (T)$. So the value of a sequential-expression $(V_1; ...; V_n; E)$ is the value of its last constituent expression E.

Sequential-expressions can be used to achieve non-functional "side effects", effectuated by the elaboration of the void-expressions, in particular the output of a message. This is useful for tracing the execution of generated code. The equivalent effect of the example above can be achieved by a let-binding:

```
let _ = writeLine "key not found" in
embed Missing
```

(If the intent is to temporarily add, and later remove or disable the tracing output, this is probably a more convenient style, as the modifications needed concern a single full text line.) Any values resulting from elaborating the void-expressions are discarded.

2.6.15. List-displays

```
list-display ::= [ list-display-body ]
list-display-body ::= [ expression { , expression }* ]
Sample list-display:
    ["Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat"]
```

Restriction. All expressions of the list-display-body must have the same sort.

Note that a list-display [] with empty list-display-body is polymorphic, and may need to be sort-disambiguated, for example with a sort annotation. In a case like [[], [1]], there is no need to disambiguate [], since the above restriction already implies that [] here has the same sort as [1], which has sort List Nat.

The parameterized sort List, although built-in, is actually not primitive, but defined by:

The empty list-display [] denotes the same list as the expression Nil, a singleton list-display [E] denotes the same list as the expression Cons (E, Nil), and a multi-element list-display [E_1 , E_2 , ..., E_n] denotes the same list as the expression Cons (E_1 , [E_2 , ..., E_n]).

2.6.16. Structors

```
structor ::=
    projector
    relaxator
    quotienter
    chooser
    embedder
    embedding-test
```

The structors are a medley of constructs, all having polymorphic or sort-ambiguous function sorts and denoting special functions that go between structurally related sorts, such as the constructors of sum sorts and the destructors of product sorts.

Restriction. Like all polymorphic or sort-ambiguous constructs, a **structor** can only be used in a context where its sort can be inferred uniquely. This restriction will not be repeated for the various kinds of **structors** described in the following subsections.

For example, the following correct spec becomes incorrect when any of the sort annotations is omitted:

2.6.16.1. **Projectors**

```
projector ::= project field-selector
```

Sample projectors:

```
project 2
project re
```

When the field-selector is some nat-literal with value i, it is required that i be at least 1. The sort of the projector is a function sort (whose domain sort is a product sort) of the form $S_1 * S_2 * ... * S_n -> S_i$, where n is at least i, and the value of the projector is the function that maps each n-tuple $(v_1, v_2, ..., v_n)$ inhabiting the domain sort to its ith component v_i .

When the field-selector is some field-name F, the sort of the projector is a function sort (whose domain sort is a record sort) of the form $\{F_1: S_1, F_2: S_2, \dots, F_n: S_n\} \rightarrow S_i$, where F is the same field-name as F_i for some natural number i in the range 1 through n. Assuming that the fields are lexicographically ordered by field-name (see under Sort-records), the value of the projector is the function that maps each n-tuple (v_1, v_2, \dots, v_n) inhabiting the domain sort to its ith component v_i .

2.6.16.2. Relaxators

```
relaxator ::= relax closed-expression
```

Sample relaxator:

```
relax even
```

Restriction. The closed-expression of a relaxator must have some function sort $S \rightarrow Boolean$.

The sort of relaxator relax P, where P has sort $S \rightarrow Boolean$, is the function sort (whose domain is a subsort) ($S \mid P$) $\rightarrow S$. The value of the relaxator is the function that maps each inhabitant of subsort ($S \mid P$) to the same value -- apart from the sort information -- inhabiting supersort S.

For example, given

```
sort Even = (Nat | even)
```

we have the sorting

```
relax even : Even -> Nat
```

for the function that injects the even natural numbers back into the supersort of Even.

Metaslang does not require the explicit use of a relaxator to relax an expression from a subsort to its supersort if the context requires the latter. Implicit relaxation will take place when needed. For example, in the expression ~1 the nat-literal 1 of sort Nat is implicitly relaxed to sort Integer to accommodate the unary negation operator ~, which has sort Integer -> Integer.

Note the remarks about equivalence of **sort-restrictions** in the corresponding section.

2.6.16.3. Quotienters

```
quotienter ::= quotient closed-expression
```

Sample quotienter:

```
quotient (fn (m, n) \rightarrow m \text{ rem } 3 = n \text{ rem } 3)
```

Restriction. Tronsihe closed-expression of a quotienter must have some sort $S * S \to Boolean$; in addition, it must be an equivalence relation, as explained under *Sort-quotients*.

The sort of quotienter quotient Q, where Q has sort S * S -> Boolean, is the function sort S -> S / Q, that is, it goes from some sort to one of its quotient sorts. The value of the quotienter is the function that maps each inhabitant of sort S to the Q-equivalence class inhabiting S / Q of which it is a member.

For example, given

```
def congMod3 : Nat * Nat -> Boolean =
  (fn (m, n) -> m rem 3 = n rem 3)
sort Z3 = Nat / congMod3
```

we have the sorting

```
quotient congMod3 : Nat -> Z3
```

and the function maps, for example, the number 5 to the equivalence class {2, 5, 8, ...}, which is one of the three inhabitants of z3.

2.6.16.4. Choosers

chooser ::= choose closed-expression

Sample chooser:

```
choose congMod3
```

Restriction. In a chooser choose Q, expression Q must have some sort $S * S \rightarrow Boolean$, and must be an equivalence relation (see under *Sort-quotients*).

The sort of a **chooser** choose Q, where Q has sort S * S -> Boolean, is a function sort of the form R -> (S /Q -> T), where R is the subsort of S -> T consisting of the Q-constant (explained below) functions. Expressed more formally, R is the sort $\{f : S -> T \mid fa((x,y) : S * S) Q(x,y) => f x = f y\}$, where the names f, f and f must be replaced by "fresh" names not clashing with names already in use in f, f or f.

The value of the **chooser** is the function mapping each Q-constant (explained below) function f inhabiting sort f -> f to the function that maps each inhabitant f of f -> f to the function that maps each inhabitant f of f -> f to the function that maps each inhabitant f of f -> f -> f to the function any member of f -> f -> f to the function any that arbitrarily picks any member from a nonempty set, this is the function

```
fn f \rightarrow fn C \rightarrow f (any C)
```

The requirement of *Q*-constancy is precisely what is needed to make this function insensitive to the choice made by any.

Function f is Q-constant if, for each Q-equivalence class C inhabiting S / Q, $f \times equals f y$ for any two values x and y that are members of C, or f is undefined on all members of C. (Since the result of f is constant across each equivalence class, it does not matter which of its elements is selected by any.) For example -- continuing the example of the previous section -- function f n -> n*n rem 3 is congMod3-constant; for the equivalence class $\{2, 5, 8, ...\}$, for example, it maps each member to the same value 1. So choose congMod3 (f n n -> n*n rem 3) maps the inhabitant $\{2, 5, 8, ...\}$ of sort z3 to the natural number 1.

The most discriminating Q-constant function is quotient Q, and choose Q quotient Q is the identity function on the quotient sort for Q.

The meaning of choose Q (fn x -> E) A is the same as that of the let-expression let quotient Q x = A in E. Indeed, often a quotient-pattern offers a more convenient way of expressing the intention of a chooser. Note, however, the remarks on the proof obligations for quotient-patterns.

2.6.16.5. Embedders

```
embedder ::= [ embed ] constructor
```

Sample embedders:

```
Nil
embed Nil
Cons
embed Cons
```

Disambiguation. If an expression consists of a single name, which, in the context, is both the name of a constructor and the name of an op or a local-variable in scope, then it is interpreted as the latter of the various possibilities. For example, in the context of

the value of which yes is "Oh, no!", since yes here is disambiguated as identifying the op yes, which has value no. The interpretation as embedder is forced by using the embed keyword: the value of which embed yes is "Yes!". By using names that begin with a capital letter for constructors, and names that do not begin with a capital letter for ops and local-variables, the risk of an accidental wrong interpretation can be avoided.

The semantics of **embedders** is described in the section on *Sort-sums*. The presence or absence of the keyword embed is not significant for the meaning of the construct (although it may be required for grammatical disambiguation, as described above).

2.6.16.6. Embedding-tests

```
embedding-test ::= embed? constructor
```

Sample embedding-test:

```
embed? Cons
```

Restriction. The sort of an embedding-test embed? C must be of the form $SS \rightarrow Boolean$, where SS is a sum sort that has a constructor C.

The value of embedding-test embed? C is the predicate that returns true if the argument value -- which, as inhabitant of a sum sort, is tagged -- has tag C, and otherwise false. The embedding-test can be equivalently rewritten as

```
fn | C _ -> true | _ -> false
```

where the wildcard _ in the first branch is omitted when C is parameter-less.

In plain words, embed? C tests whether its sum-sorted argument has been constructed with the constructor C. It is an error when C is not a constructor of the sum sort.

2.7. Matches and Patterns

2.7.1. Matches

```
match ::= [ | ] branch { | branch }*

branch ::= pattern -> expression

Sample matches:
    {re = x, im = y} -> {re = x, im = ~y}

        Empty -> true
        Push {top = _, pop = rest} -> hasBottom? rest
```

```
| Empty -> true
| Push {top = _, pop = rest} -> hasBottom? rest
```

Restriction. In a match, given the environment, there must be a unique sort S to which the pattern of each branch conforms, and a unique sort T to which the expression of each branch conforms, and then the match has sort $S \rightarrow T$. The pattern of each branch then has sort S.

Disambiguation. If a branch could belong to several open matches, it is interpreted as being a branch of the textually most recently introduced match. For example,

is not interpreted as suggested by the indentation, but as

If the other interpretation is intended, the expression introducing the inner match needs to be parenthesized:

Acceptance and return value y, if any, of a value x for a given match are determined as follows. If each branch of the match rejects x (see below), the whole match rejects x, and does not return a value. Otherwise, let x stand for the textually first branch accepting x. Then y is the return value of x for x.

Acceptance and return value y, if any, of a value x for a branch $P \rightarrow E$ in an environment C are determined as follows. If pattern P rejects x, the branch rejects x, and does not return a value. (For acceptance by a pattern, see under *Patterns*.)

Chapter 2. Metaslang

Otherwise, y is the value of expression E in the environment C extended with the acceptance binding of pattern P for x.

For example, in

if z has value (3, true), the first branch accepts this value with acceptance binding x = 3. The value of Some x in the extended environment is then Some 3. If z has value (3, false), the second branch accepts this value with empty acceptance binding (empty since there are no "accepting" local-variables in pattern ($_$, false)), and the return value is None (interpreted in the original environment).

2.7.2. Patterns

```
pattern ::=
        annotated-pattern
     tight-pattern
tight-pattern ::=
        aliased-pattern
       cons-pattern
       embed-pattern
       quotient-pattern
       relax-pattern
       closed-pattern
closed-pattern ::=
       variable-pattern
       wildcard-pattern
       literal-pattern
       list-pattern
       tuple-pattern
       record-pattern
     ( pattern )
```

(As for expressions, the distinctions tight- and closed- for patterns have no semantic significance, but merely serve to avoid grammatical ambiguities.)

```
annotated-pattern ::= pattern : sort
```

```
aliased-pattern ::= variable-pattern as tight-pattern
cons-pattern ::= closed-pattern :: tight-pattern
embed-pattern ::= constructor [ closed-pattern ]
quotient-pattern ::= quotient closed-expression tight-pattern
relax-pattern ::= relax closed-expression tight-pattern
variable-pattern ::= local-variable
wildcard-pattern ::= _
literal-pattern ::= literal
list-pattern ::= [ list-pattern-body ]
list-pattern-body ::= [ pattern { , pattern }* ]
tuple-pattern ::= ( tuple-pattern-body )
tuple-pattern-body ::= [ pattern , pattern { , pattern } * ]
record-pattern ::= { record-pattern-body }
record-pattern-body ::= [ field-patterner { , field-patterner }* ]
field-patterner ::= field-name [ equals pattern ]
Sample patterns:
     (i, p) : Integer * Boolean
    z as {re = x, im = y}
    hd :: tail
    Push {top, pop = rest}
    embed Empty
    quotient congMod3 n
    relax even e
    X
    #z
    [0, x]
```

```
(c1 as (0, _), x) {top, pop = rest}
```

Restriction. Like all polymorphic or sort-ambiguous constructs, a pattern may only be used in a context where its sort can be uniquely inferred.

Disambiguation. A single name used as a pattern is an embed-pattern if it is a constructor of the sort of the pattern. Otherwise, the name is a variable-pattern.

Restriction. Each local-variable in a pattern must be a different name, disregarding any local-variables introduced in expressions or sorts contained in the pattern. (For example, Line (z, z) is not a lawful pattern, since z is repeated; but $n : \{n : Nat \mid n < p\}$ is lawful: the second n is "shielded" by the sort-comprehension in which it occurs.)

Restriction. The closed-expression of a quotient-pattern must have some sort $S * S \to Boolean$; in addition, it must be an equivalence relation, as explained under *Sort-quotients*.

Restriction. Quotient-patterns may only be used in a definition or claim if the result is insensitive to the choice of representative from the equivalence class. Specware 4.0 does not attempt to generate proof obligations for establishing this.

Restriction. The closed-expression of a relax-pattern must have some function sort $S \rightarrow Boolean$.

To define acceptance and acceptance binding (if any) for a value and a pattern, we introduce a number of auxiliary definitions.

The *expressive descendants* of a pattern are a finite set of expressions having the syntactic form of patterns, as determined in the following three steps (of which the order of steps 1 and 2 is actually immaterial).

Step 1. From pattern P, form some *tame variant* P_t by replacing each field-patterner consisting of a single field-name F by the field-patterner F = F and replacing each wildcard-pattern _ in P by a unique fresh name, that is, any name that does not already occur in the spec, directly or indirectly through an import. For example, assuming that the name $\sqrt{7944}$ is fresh, a tame variant of

```
s0 as _ :: s1 as (Push {top, pop = rest}) :: ss
```

is

```
s0 as v7944 :: s1 as (Push {top = top, pop = rest}) :: ss
```

Step 2. Next, from P_t , form a (tamed) construed version P_{tc} by replacing each constituent cons-pattern H: T by the embed-pattern Cons (H, T), where Cons denotes the constructor of the parameterized sort List. For the example, the construed version is:

```
s0 as Cons (v7944, s1 as Cons (Push \{top = top, pop = rest\}, ss))
```

Step 3. Finally, from P_{tc} , form the set ED_p of *expressive descendants* of P, where expression E is an expressive descendant if E can be obtained by repeatedly replacing some constituent aliased-pattern E as E of E one of the two patterns E and E until no aliased-patterns remain, and then interpreting the result as an expression. For the example, the expressive descendants are the three expressions:

```
s0 Cons (v7944, s1) Cons (v7944, Cons (Push \{top = top, pop = rest\}, ss))
```

An *accepting binding* of a pattern P for a value x in an environment C is some binding B of sorted values to the accepting local-variables of the *tame* variant P_t , such that the value of each expressive descendant E in ED_p in the environment C extended with binding B, is the same sorted value as x.

Acceptance and acceptance binding, if any, for a value x and a pattern P are then determined as follows. If there is no accepting binding of P for x, x is rejected. If an accepting binding exists, the value x is accepted by pattern P. There is a unique binding B among the accepting bindings in which the sort of each assigned value is as "restricted" as possible in the subsort-supersort hierarchy without violating well-sortedness constraints (in other words, there are no avoidable implicit relaxations). The acceptance binding is then the binding B projected on the accepting local-variables of P.

For the example, the accepting local-variables of P_{t} are the six local-variables s0, s1, ss, rest and v7944. In general, they are the accepting local-variables of the

Chapter 2. Metaslang

original pattern together with any fresh names used for taming. Let the value x being matched against the pattern be

```
Cons (Empty, Cons (Push {top = 200, pop = Empty}, Nil))
```

Under the accepting binding

```
s0 = Cons (Empty, Cons (Push {top = 200, pop = Empty}, Nil))
s1 = Cons (Push {top = 200, pop = Empty}, Nil)
ss = Nil
top = 200
rest = Empty
v7944 = Empty
```

the value of each E in ED_p amounts to the value x. Therefore, x is accepted by the original pattern, with acceptance binding

```
s0 = Cons (Empty, Cons (Push {top = 200, pop = Empty}, Nil))
s1 = Cons (Push {top = 200, pop = Empty}, Nil)
ss = Nil
top = 200
rest = Empty
```

obtained by "forgetting" the fresh name v7944.

Appendix A. Metaslang Grammar

This appendix lists the grammar rules of the Metaslang specification language. These rules are identical to those of the Chapter on *Metaslang*. They are brought together here, without additional text, for easy reference.

Appendix A. Metaslang Grammar

The base libraries are automatically imported by every user-defined spec.

This appendix provides a brief description of the sorts and ops in the current base libraries. The title of each section of this appendix is the qualifier of the sort-names and op-names given therein. For example, the full op-name for op ~ described in Section "Boolean" is Boolean. ~.

B.1. Boolean

Sort

sort Boolean

Name	Fixity	Sort	Description
~		Boolean -> Boolean	logical negation
&	infixr	Boolean * Boolean -> Boolean	logical and
or	infixr	Boolean * Boolean -> Boolean	logical or
=>	infixr	Boolean * Boolean -> Boolean	logical implication
<=>	infixr	Boolean * Boolean -> Boolean	logical equivalence
~=	infixr	fa(a) a * a -> Boolean	inequality (logical exclusive or)

Name	Fixity	Sort	Description
toString	3	Boolean -> String	converts Boolean value to string
show		Boolean -> String	same as toString
compare		Boolean * Boolean -> Comparison	compares two Boolean values

B.2. Integer

Sorts

```
sort Integer
sort NonZeroInteger = {i : Integer | i ~= 0}
```

Name	Fixity	Sort	Description
~		Integer -> Integer	unary minus
+		Integer * Integer ->	addition
	infixl	Integer	
	25		
_		Integer * Integer ->	subtraction
	infixl	Integer	
	25		

Appendix B. Base Libraries

Name	Fixity	Sort	Description
*	infixl 27	Integer * Integer -> Integer	multiplication
div	infixl 26	<pre>Integer * NonZeroInteger -> Integer</pre>	division (truncates towards 0)
rem	infixl 26	Integer * NonZeroInteger -> Integer	remainder $(x \text{ rem } y = x - y $ * $(x \text{ div } y))$
<	infixl	Integer * Integer -> Boolean	less-than
<=	infixl	Integer * Integer -> Boolean	less-than-or-equal
>	infixl	Integer * Integer -> Boolean	greater-than
>=	infixl	Integer * Integer -> Boolean	greater-than-or-equal
abs		Integer -> Integer	absolute value
min		<pre>Integer * Integer -> Integer</pre>	minimum
max		Integer * Integer -> Integer	maximum
compare		Integer * Integer -> Comparison	compares two integers
toString		Integer -> String	converts integer to string
show		Integer -> String	same as toString
intToStrir	ıg	Integer -> String	same as toString

Name		Sort	Description
	Fixity		-
intConvert	ible	String -> Boolean	tests if string is representation of integer
stringToIr	ıt.	(String intConvertible) -> Integer	converts "convertible" string to integer

B.3. Nat

Sorts

```
sort Nat = \{n : Integer \mid n >= 0\}
sort PosNat = \{n : Nat \mid n > 0 \}
```

Name	Fixity	Sort	Description
succ		Nat -> Nat	successor
pred		Nat -> Integer	predecessor
zero		Nat	the natural number 0
one		Nat	the natural number 1
two		Nat	the natural number 2
posNat?		Nat -> Boolean	yields false for 0, true otherwise
toString		Nat -> String	converts natural number to string
show		Nat -> String	same as toString

Name	Fixity	Sort	Description
natToStrir	ıg	Nat -> String	same as toString
natConvert	ible	String -> Boolean	tests if string is representation of natural number
stringToNa	ıt	(String natConvertible) -> Nat	converts "convertible" string to natural number

B.4. Char

Sort

sort Char

Name	Fixity	Sort	Description
ord		Char -> Nat	converts character to natural number
chr		Nat -> Char	converts natural number to character
isAlpha		Char -> Boolean	true for letters
isNum		Char -> Boolean	true for digits
isAlphaNur	n	Char -> Boolean	true for letters and digits
isAscii		Char -> Boolean	true for ASCII characters

Name F	ixity	Sort	Description
isLowerCase	2	Char -> Boolean	true for lower-case letters
isUpperCase	2	Char -> Boolean	true for upper-case letters
toUpperCase	2	Char -> Char	converts to upper case
toLowerCase	2	Char -> Char	converts to lower case
compare		Char * Char -> Comparison	compares two character values
toString		Char -> String	converts character to string
show		Char -> String	same as toString

B.5. String

Sort

sort String

Name	Fixity	Sort	Description
explode		String -> List(Char)	converts string to list of characters

Appendix B. Base Libraries

Name	Fixity	Sort	Description
implode		List(Char) -> String	converts list of characters to string
length		String -> Nat	length of a string
leq	infixl 20	String * String -> Boolean	less-than-or-equal
lt	infixl	String * String -> Boolean	lexicographic less-than
++	infixl	String * String -> String	string concatenation
^	infixl	String * String -> String	same as ++
concat		String * String -> String	prefix op for string concatenation
concatList	,	List String -> String	returns the concatenation of the list elements
sub		String * Nat -> Char	returns the <i>n</i> th character in a string, counting from 0
substring		String * Nat * Nat -> String	substring(s, m, n) returns the substring of s from position m through position n-1, counting from 0
map		(Char -> Char) * String -> String	returns the concatenation of the results of applying the function given as first parameter to each character of the string
translate		(Char -> String) * String -> String	returns the concatenation of the results of applying the function given as first parameter to each character of the string

Name	Fixity	Sort	Description
all		(Char -> Boolean) * String	true if all characters in the string satisfy the predicate given as first parameter
exists		(Char -> Boolean) * String	true if some character in the string satisfies the predicate given as first parameter
newline		String	the string representing a line break
toScreen		String -> ()	prints the string on the terminal
writeLine		String -> ()	same with a newline appended
compare		String * String -> Comparison	compares two strings

B.6. List

Sort

sort List a = | Nil | Cons a * List a

Name	Fixity	Sort	Description
nil		fa(a) List a	the empty list
null		fa(a) List a -> Boolean	true for empty lists
length		List a -> Nat	length of a list

Appendix B. Base Libraries

Name	Fixity	Sort	Description
cons		fa(a) a * List a -> List a	constructs a list consisting of a first element and a list tail
insert		fa(a) a * List a -> List a	same as cons
hd		fa(a) List a -> a	returns the first element of the list
tl		fa(a) List a -> List a	returns the list tail without the first element
++	infixl	fa(a) List a * List a -> List a	list concatenation
@	infixl	fa(a) List a * List a -> List a	same as ++
concat		fa(a) List a * List a -> List a	prefix op for list concatenation
flatten		fa(a) List(List(a)) -> List a	returns the concatenation of the list elements
diff		fa(a) List a * List a -> List a	list subtraction: $diff(x,y)$ returns a list containing the elements of x that are not in y , preserving the order of the elements in x
member		fa(a) a * List a -> Boolean	list membership
nth		fa(a) List a * Nat -> a	nth(x, n) returns the element at position n of list x , counting from 0
nthTail		fa(a) List a * Nat -> List a	nthTail(x , n) returns the tail of list x , starting after position n , counting from 0
sublist		fa(a) List a * Nat * Nat -> List a	sublist(x, m, n) returns the tail of list x, from position m up to but not including n, counting from 0

Name	Fixity	Sort	Description
foldl		fa(a,b) (a*b -> b) -> b -> List a -> b	foldl $f \in x$ successively applies function f to the elements of list x from left to right. The second argument to f is initially e and at each next step the result of the previous invocation of f
foldr		fa(a,b) (a*b -> b) -> b -> List a -> b	like fold1, but the elements of the list are processed from right to left
map		fa(a,b) (a->b) -> List a -> List b	applies function to each element of a list and returns the list consisting of the results
mapPartial	-	fa(a,b) (a->Option b) -> List a -> List b	like map but replacing each result Some y by y and deleting None results.
filter		fa(a) (a -> Boolean) -> List a -> List a	returns the list of elements satisfying the given predicate
rev		fa(a) List a -> List a	reverse list
all		fa(a) (a -> Boolean) -> List a -> Boolean	true if all elements of the list satisfy the predicate given as first parameter
exists		fa(a) (a->Boolean) -> List a -> Boolean	true if some element of the list satisfies the predicate given as first parameter
find		fa(a) (a -> Boolean) -> List a -> Option(a)	returns Some x where x is the first element in the list (from left to right) for which the given predicate yields true; if no such element exists, None is returned
tabulate		fa(a) Nat * (Nat -> a) -> List a	tabulate(n , f) returns the list [$f(0)$, $f(1)$,, $f(n-1)$]

Appendix B. Base Libraries

Name	Fixity	Sort	Description
firstUpTo		fa(a) (a -> Boolean) -> List a -> Option (a * List a)	returns Some (e, x) where e is the first element in the list (from left to right) satisfying the given predicate and x the initial list segment preceding e; if no such element exists, None is returned
splitList		fa(a) (a -> Boolean) -> List a -> Option (List a * a * List a)	returns Some(x, e, y) where e is the first element in the list (from left to right) satisfying the given predicate, x the initial list segment preceding e, and y the list tail following e; if no such element exists, None is returned
locationOf	-	fa(a) List a * List a -> Option (Nat * List a)	locationOf(s, t) returns Some(n, x) where n is the first position in list t (counting from from left to right) where list s occurs as a contiguous sublist, and x the list tail segment following s in t; if s does not occur in t, None is returned
compare		<pre>fa(a) (a * a -> Comparison) -> List a * List a -> Comparison</pre>	compares two list using the comparison function given as first parameter
show		fa(a) String -> List String -> String	show(s, x) returns the element strings in x concatenated, with string s inserted between any two elements

B.7. Compare

Sort

sort Comparison = | Less | Equal | Greater

Ops

Name		Sort	Description
	Fixity		-
compare		Comparison *	compares comparison values
		Comparison ->	
		Comparison	
show		Comparison -> String	converts comparison value to
			string

B.8. Option

Sort

sort Option a = | Some a | None

Name	Fixity	Sort	Description
some		fa(a) a -> Option a	op that constructs Some x
none		fa(a) Option a	op that constructs None
some?		fa(a) Option a ->	tests if the parameter is of the
		Boolean	form Some x

Name	Fixity	Sort	Description
none?		fa(a) Option a -> Boolean	tests if the parameter is None
compare		<pre>fa(a) (a * a -> Comparison) -> Option a * Option a -> Comparison</pre>	returns the result of the comparison of the two optional values, where None is less than Some x for all x ; if both optional values are of the form Some x , the comparison function given as first parameter is used to compute the result
mapOption		fa(a,b) (a -> b) -> Option a -> Option b	applies the function given as first parameter to the optional value if it is Some x, otherwise None is returned
show		<pre>fa(a,b) (a -> String) -> Option a -> String</pre>	converts optional value to string; if the optional value is Some x, it uses the function given as first parameter to convert x to a string

B.9. Functions

Sorts

```
sort Injective(a,b) = ((a -> b) | injective?)
sort Surjective(a,b) = ((a -> b) | surjective?)
sort Bijective(a,b) = ((a -> b) | bijective?)
```

Name	Fixity	Sort	Description
id		fa(a) a -> a	identity function
0	infixl	fa(a,b,c) (b -> c) * (a -> b) -> (a -> c)	function composition
injecti	ve?	fa(a,b) (a -> b) -> Boolean	injectivity predicate; non-constructive
surject	ive?	fa(a,b) (a -> b) -> Boolean	surjectivity predicate; non-constructive
bijecti [.]	ve?	fa(a,b) (a -> b) -> Boolean	bijectivity predicate; non-constructive
inverse		<pre>fa(a,b) Bijective(a,b) -> Bijective(b,a)</pre>	inverts bijective function; non-constructive
